FAO also distinguishes forests managed primarily for their ecosystem services, principally coastal stabilization, clean water, erosion control, and desertification. Statistics reported from some countries go well beyond protected areas: 71% of forests in North and Central America managed for soil and water protection; 80% of forests in Uzbekistan managed for erosion control (Food and Agriculture Organization of the United Nations (FAO), 2018); and so on. These general designations are not all protected areas and not considered here.

What Do Forest Protected Areas Provide?

Protected areas are designated primarily for nature conservation, which includes all aspects of biodiversity (ecosystems, species and intra-specific genetic variation) and also geodiversity, geology, and landforms. Over time, the sophistication of protected areas selection has increased, from an initial focus on rare species, such as pandas in Sichuan, to consideration of ecosystems, gap analysis (Dudley and Parrish, 2006), biodiversity richness, irreplaceability (Ferrier et al., 2000), connectivity (Beier et al., 2008), and extinction risk (Ricketts et al., 2005). The key biodiversity area (KBA) concept emerged as a unifying measure, defined as "sites contributing significantly to the global persistence of biodiversity" (IUCN, 2016). It is not always necessary to designate all or any part of a KBA as a protected area to maintain its biodiversity values, but the existence of a KBA is an important factor in protected

Table 3 Estimates for area and proportion of forests within protected areas listed by the UN

<i>Realm</i>	<i>Natural forest area (km²)</i>	<i>Forests in protected areas (km²)</i>	<i>Forests in protected areas (%)</i>
Australasia	1,787,015	395,644	22.1
Afrotropic	6,818,852	1,198,400	17.6
Indo-Malayan	2,568,626	457,534	17.8
Nearctic	7,314,463	748,839	10.2
Neotropical	8,754,932	3,466,784	39.6
Oceanian	5836	781	13.4
Palaearctic	11,827,242	1,580,800	13.4
World	39,076,966	7,848,782	20.1

Juffe-Bignoli, D., Burgess, N. D., Bingham, H., Belle, E. M. S., de Lima, M. G. et al. (2014). *Protected planet report 2014*. Cambridge: UNEP World Conservation Monitoring Centre.

area planning (Smith et al., 2018). The proportion of KBAs in protected areas is increasing, although no separate analysis has been carried out for forested KBAs (Food and Agriculture Organization of the United Nations (FAO), 2018).

The existence of better planning tools does not necessarily mean that protected areas are always designated according to conservation criteria. Social, commercial and political influences remain important. But there is increasing interest in choosing forests that are the most significant for biodiversity. The concept of representativeness, ensuring that all ecosystems and species are represented in protected areas, has also assumed higher importance.

Although protected areas prioritize nature conservation, the IUCN definition refers to “associated ecosystem services and cultural values” (Dudley, 2008). These values have a growing role in determining the designation and management of forest protected areas.

The Millennium Ecosystem Assessment grouped ecosystem services into four categories of supporting, provisioning, regulating and cultural services (Millennium Ecosystem Assessment, 2005). Supporting services are ecosystem processes and functions that keep life on the planet running: soil formation and nutrient cycling; lifecycle maintenance by for instance providing fish nursery habitats; seed dispersal and other species interactions; and biodiversity conservation. Provisioning services are the tangible resources that ecosystems provide directly or help to support and include contributions to food and water security, and access to raw materials, medicines and other genetic resources. Regulating services refer mainly to the role of natural ecosystems in helping control extreme weather events, the water cycle, earth movements, and natural processes that impact on agriculture such as pollination. They include the role of ecosystems in storing and sequestering carbon, thus reducing the rate of climate change. Finally, cultural services refer to the many cultural, psychological, and spiritual links that humans have with the natural world and range from aesthetic appreciation to religious associations.

Forest protected areas supply multiple ecosystem services (Stolton and Dudley, 2010). They are critical to supporting services, as sources of soil and water, maintenance of pollinators and other biodiversity for food and agriculture and through driving key aspects of the global weather cycle. For example, circulation of billions of tonnes of water vapor from the Amazon forest has been termed the “flying rivers” of the Amazon, providing water for agricultural areas further south (Nobre, 2014). Globally, almost 9.5% of forests are managed primarily for soil and water conservation (Food and Agriculture Organization of the United Nations (FAO), 2018), although it is not clear how much of this is in protected areas.

Forest protected areas play a critical role in many provisioning services, particularly related to water and food security. Natural forest ecosystems generally produce purer water from their catchments than most other land uses, partly because less polluting activities take place within forests and partly due to ecological processes that remove some pollutants (Dudley and Stolton, 2003). A smaller proportion of forests, principally tropical mountain cloud forests, also increase the net water flow from the catchment (Hamilton and King, 1983). The role of forest protected areas in supplying drinking water is recognized; a third of the world’s top 100 cities draw a significant proportion of their water from forest protected areas (Dudley and Stolton, 2003).

Forest protected areas also supply a certain amount of food, through managed collection by local people and sometimes because game species spill over from protected forests into the wider landscape. However, illegal hunting of bushmeat in protected areas, whilst understandable as a source of protein and money for poor communities currently undermines the effectiveness of many protected areas as discussed below.

The role of forest protected areas in regulating services is more varied, and includes stabilizing soils, rocks and snow and thus reducing landslide and avalanche, coastal protection from mangroves, and riparian forests to mitigate flood events and store water to release more gradually during periods without rain (Kumagai et al., 2013). FAO estimates that 1% of global forests are managed for coastal protection, while countries like Tajikistan consciously manage forests on steep slopes to reduce avalanches (Food and Agriculture Organization of the United Nations (FAO), 2018). Increasingly important is the role of forests and forest soils in storing and sequestering carbon (Keith et al., 2009). Research shows that forests continue to store carbon even in old-growth phase by building up soil stocks (e.g., Keith et al., 2009; Lewis et al., 2009), while removing or burning forests results in an abrupt spike of carbon loss. Protected areas have an important and increasingly recognized role in maintaining carbon stocks (Dudley et al., 2009), particularly those centered on primary forests (Mackey et al. 2014).

Cultural ecosystem services cover benefits ranging from tourism to spiritual fulfillment. The tourism values of forests include local amenity, walking and outdoor sports, landscape values and nature tourism. Tourism is replacing agriculture and forestry as a rural source of income in many areas and for countries like Rwanda can be the largest earner of foreign exchange (Sabuhoro

et al., 2017). Some forest protected areas contain important buildings, such as temples or prehistoric sites, in other cases forest management systems can themselves be of historical significance. Forests in many countries contain spiritual and aesthetic values to faith groups, including the existence of sacred trees and groves (e.g., Salick et al., 2007). Given that most protected area managers come from a scientific background, managing cultural, historical and sacred sites often means learning new skills and working with new partners. Guidelines tailored to protected areas are becoming more readily available (e.g., Wild and McLeod, 2008).

Social Dimensions of Forest Protected Areas

Protected areas also have a human dimension in terms of people who visit them, rely on their ecosystem services and most importantly who live in and around protected areas. Human interactions with protected areas have not always been straightforward. When establishing protected areas, many countries introduced legislation stating that they should be empty of human habitation, with all resource uses banned. This caused immediate problems in those ecosystems where people were living. Over 20 years ago, estimates in Latin America found that 86% of national parks contained human habitation (Amend and Amend, 1995). Where they occurred, forced relocations, sometimes without adequate (or any) compensation, created a social crisis and people with nowhere else to go frequently continued to occupy protected areas illegally, poaching species they had traditionally hunted. Critics accuse some protected areas of serious human rights abuses (Brockington et al., 2008). Conversely, and adding further complication, in successful protected areas where wildlife numbers remain high, new settlers are sometimes drawn by the possibility of a large bushmeat harvest.

In the last 20 years, and particularly following the 2003 World Parks Congress (IUCN, 2005), many countries have worked hard to address social inequalities in protected areas through changing legislation, working with local communities, developing realistic compensation packages and negotiating access and user rights. While problems remain, global experience in reconciling protected areas and people is far more advanced. Many protected areas have forged new and positive relationships with indigenous peoples, working in partnership rather than in opposition (Stevens, 2014). Processes such as Free, Prior and Informed Consent (Ward, 2011) and the *United Nations Declaration on the Rights of Indigenous People* (UN, 2007) raise expectations for a strong human rights approach in conservation and provide tools to help achieve this.

When they work well, forest protected areas provide many social benefits; in terms of the range of ecosystem services and in many cases also safe places to live for vulnerable human communities. But poorly planned, top-down protected areas can result in significant displacement and loss of livelihoods, creating tensions, and usually a backlash in the form of illegal occupation and use and sometimes direct vandalism and threats to managers and rangers. These problems are not confined to protected areas and occur even more acutely under other management regimes; responsibly managed protected areas can indeed provide a model suitable for application in the wider landscape.

Management Effectiveness—Do Forest Protected Areas Work?

Rapid expansion of protected area has meant an equally rapid development in terms of management, and a growing number of protected areas are assessing management effectiveness as a standard part of annual planning. Effectiveness in forest protected areas needs to consider two distinct issues: whether a forest protected area is an effective way of keeping the forest intact; and whether it is effective in conserving the constituent biodiversity.

Protected areas are not perfect mechanisms and continued degradation often takes place, particularly at the boundaries as people chip away at forests for fuelwood, building materials or to create farmland. Pressures include land conversion, infrastructure development (particularly roads), poaching and over-collection but also sometimes factors such as visitor pressure, air and water pollution and, increasingly important, climate change.

Nonetheless, research shows that protected areas are amongst the most effective ways of maintaining native forests. A study in 22 tropical countries concluded that most protected areas are successful in protecting ecosystems (Bruner et al., 2001) while research in the Amazon (Asner et al., 2005) and in a variety of tropical countries (Joppa et al., 2008) found forest protected areas are generally effective in maintaining forest cover. A global review by the World Bank found that tropical protected areas, especially those conserved by indigenous peoples lose less forest than other management systems (Nelson and Chomitz, 2009).

Whether or not forest protected areas maintain their constituent biodiversity is less clear. Serious problems of species loss in protected areas is well known (Grumbine, 1990) and the phenomenon of “empty forests,” where most wildlife has been removed through over-collection and poaching, has long been recognized (Redford, 1992). Bushmeat hunting remains a critical threat in large forest areas of Asia, Africa and Latin America. Recent research identified poaching as a significant factor in the decline of 301 terrestrial mammal species threatened with extinction (Ripple et al., 2016). Retention of the constituent ecosystem makes it much easier to recover species numbers or to reintroduce species if pressures are reduced; this is occurring in many parts of Europe for example where populations of large mammals are recovering slowly from historical lows. However, the current pressures within some forest protected areas, for example in Vietnam (Drury, 2011) and parts of West Africa (McNamara et al., 2015), remain extremely severe.

The Future of Forest Protected Areas

Depending on the estimates taken, the world already has up to a fifth of its native forests in protected areas. These global figures mask regional disparities. For instance, the Neotropical zone has double the global average while Oceania, the Nearctic and Palearctic have significantly less (see [Table 3](#)). At a finer level of analysis many particular forest types, and ecoregions, remain poorly protected. Wilderness areas and the most intact forests continue to decline ([Watson et al., 2016](#)) despite the high biodiversity values maintained within intact forests ([Watson et al., 2018](#)). Deforestation continues apace and the conservation organization WWF has identified 10 deforestation fronts, where the majority of deforestation will likely occur until 2030 ([Taylor et al., 2015](#)). Furthermore, the long-term security of many forest protected areas remains uncertain. A rise in populist politicians, often proclaiming an explicitly anti-environmental message, could see many of the conservation gains of the last two decades rolled back again unless conservation advocates can find new arguments to persuade skeptical and powerful people of the value of natural forests.

Conversely, the importance of protected areas is generally recognized around the world ([Watson et al., 2014](#)). Despite the rhetoric from a handful of influential governments, the global consensus on the reality and seriousness of climate change continues to grow. The value of maintaining native ecosystems as a bulwark against rapid environmental change is gaining increasing recognition ([Olson et al., 2012](#); [Watson et al., 2013](#)), both from the perspective of carbon storage ([Grassi et al., 2017](#)) and the wider issues of ecosystem services ([Stolton and Dudley, 2010](#)). Forest protected areas will hopefully continue to play a pivotal role in helping to maintain global biodiversity and other ecosystem services into the future.

Abstract

Leadership forest certification systems can provide valuable independent measures of more ecologically, socially, and economically sustainable forest management, thereby empowering businesses and other consumers wishing to make informed purchasing decisions for forest products, supporting resource managers who use and adopt leadership forest and ecosystem management practices, and contributing to broader discussions over resource management and conservation. However, questions remain over which forest certification systems merit recognition as leadership systems, the limits of any certification systems' abilities to (by themselves) halt global deforestation and achieve other outcomes, and how certification systems will respond to climate change and other priority and emerging challenges. This article introduces the concepts and basic components of forest certification, outlines considerations for researchers wishing to compare certification systems, and highlights other topics of interest for the evolution of certification and its role in responsible forest management, forest conservation, and sustainable business practices.

Basic Concept, Goals, and Approaches

While the function and significance of forest certification can depend on one's perspective, a good starting point is to think of it as a market-based mechanism for distinguishing wood, paper, rubber, tree nuts, and other forest products associated with more environmentally, socially, and economically desirable and exemplary forest management. Certification systems like the Forest Stewardship Council (FSC) are meant to enable consumers and businesses to identify and purchase products from timber companies, community forests, Indigenous Peoples, and other forest managers who follow the system's forestry standards, thus also enabling them to avoid products from deforestation and other harmful practices.

Long the pre-eminent forest certification system, the FSC has also been a leader within the broader eco-labeling movement and, to varying degrees, a model for other systems. Indeed, systems like the Marine Stewardship Council and Sustainable Agriculture Network were largely inspired by the FSC. The FSC was established in 1993 by environmental and social non-governmental organizations (NGOs), forest sector businesses, and other nascent eco-forestry initiatives. Their interests included concerns with tropical deforestation, loss of old growth and other primary forests, degradation of forest ecosystems, injustices in the forestry sector against Indigenous Peoples and other at-risk social groups, and/or insufficient market recognition for more sustainable forestry practices.

From an economics and public policy perspective, leadership certification systems embody the potential for helping to correct existing markets' and regulatory systems' failure to account for important environmental and social impacts, and long-term economic sustainability (i.e., environmental and social externalities). Such leadership systems also embody an implicit goal of empowering consumers to make informed and responsible purchasing decisions. Whether individuals will choose to exercise their economic "votes" is another question, and in some markets (e.g., the United States), the evolution of corporate sustainability and procurement programs has done far more to create market demand for certified forest products. As discussed in [Conroy \(2007\)](#) and elsewhere, the NGO advocacy campaigns that helped motivate these corporate programs have also advanced leading certification systems, including as an alternative to sourcing products from endangered ecosystems.

Unlike some other certification systems, transparency, balanced stakeholder input and governance, and democratic decision-making have been core values in the FSC's design. This is evidenced most dramatically at the triennial General Assemblies (GAs) of the FSC's governing membership. As such, the FSC is an imperfect and cumbersome, but surprisingly successful experiment. Indeed, the system's credibility and role as a leading international voice on forestry topics is probably due largely to its efforts at governance by a membership that balances environmental, social, and economic voices, including from both developed and developing nations.

Today, the following are among the FSC's basic components. Some of these elements are also found in competing forestry schemes, while others are not, or are not employed as effectively.

- An independent, non-governmental institution that officially comprises and manages the system on a day-to-day basis.
- High-order governance of the system by a balance of environmental, social, and economic stakeholders and experts. In the FSC's case, by international and national memberships, and by international and national boards of directors elected by the membership bodies.
- Forest management standards developed by a balance of environmental, social, and economic stakeholders and experts, and approved by the system's governing bodies, to provide independent objectives and thresholds for environmentally, socially, and economically well-managed forests. The FSC's standards include internationally-applicable Principles and Criteria (P&C), and more granular national/regional Indicators that address variations in forest ecosystems and other contexts, and that are used to assess forest managers' compliance with the P&C.
- On-product certification labels, including: "FSC 100%," for products wholly from FSC certified forests; "FSC Mix," for product lines partially from certified forests; and "FSC Recycled," for products wholly from recycled or reclaimed sources.
- A process for auditing and certifying the forest management practices of participating forestry companies and other forest managers. Third-party certification bodies (CBs) are hired to evaluate participants' management systems and on-the-ground operations. Products from forest units that meet the FSC's forest standards may be marketed with a corresponding label.
- "Chain of custody" (CoC) certification and related quality control mechanisms, to ensure that labeled products originate from certified forests, and to prevent and correct any fraudulent claims. All entities in the supply chain for FSC products must be CoC certified.
- A quality control mechanism for CBs and their audits. Accreditation Services International (ASI) accredits and audits CBs on behalf of FSC.
- Additional consultation, transparency, and dispute resolution provisions. Public consultation is required during development of FSC standards and during FSC certification audits, for example. The FSC also publishes summaries of audit reports, and uses channels such as its GAs and board meeting reports for open communication with its multi-stakeholder membership. Certificate holders, national FSC offices, and FSC and ASI must also respond to appeals of certification decisions or other complaints.

In a sense, certification systems can themselves be certified. The International Standards Organization (ISO) establishes basic best practices and technical procedures for certification systems in all sectors (see the standards of the ISO Committee on Conformity Assessment (CASCO)). The ISEAL Alliance also maintains Codes of Good Practice for certification systems. This topic and others are covered in more detailed introductions to forest certification, for example, [Nussbaum and Simula \(2013\)](#).

Evaluating and Comparing Forest Certification Systems

The extent to which different certification systems require significant improvements in forest conservation and management, protect social and cultural values, and embody leadership approaches in their governance, auditing procedures, and other components is an important topic with much room for further study. In many regions, stiff competition has emerged in the forest certification sector, including from systems initiated by industry trade associations and governments in support of forest practices much closer to business-as-usual norms. (For more on the origins of such systems, see [Nussbaum and Simula \(2013\)](#) and [Ozinga \(2004\)](#).) As a result, consumers and businesses wishing to make responsible and informed purchasing decisions can no longer simply look for a forestry eco-label, but must also distinguish between certification systems and labels. Ironically, the systems with the lowest standards may also have the most readily available and widely labeled products.

Some existing comparisons of different forest certification systems are of note, both for their findings and their analytical approaches. For example, [Ozinga \(2004\)](#) and [Ford and Jenkins \(2011\)](#) provide a look at various systems from the perspective of leading conservation and social NGOs, are informative on considerations for evaluating different systems, and illustrate the importance of considering sources outside of academia. [Smith and Perreault \(2017\)](#) compare the FSC and Sustainable Forestry Initiative (SFI) from the perspective of Indigenous Peoples, and touch on the question of whether competition between systems has been productive. [Judge-Lord et al. \(2018\)](#) provide an academically robust comparison, and discuss the role of certification relative to other governance mechanisms. Meanwhile, [Clark and Kozar \(2011\)](#) is an example of a comparison based on a meta-analysis of other studies.

When comparing and evaluating forest certification systems, one may wish to give particular attention to research questions that focus on priority forest management and conservation topics, and on elements of certification systems that are especially important to their credibility and effectiveness. Opportunities to utilize more readily available data may also be of interest. With this in mind, [Appendix IA](#) highlights some research considerations regarding certification systems' institutions and governance. Examples of topics covered in the Appendix include how the systems were established and whether they are governed by open, multi-stakeholder memberships, are transparent and accountable, and meet the ISO and ISEAL best practices for certification systems.

Similarly, [Appendix IB](#) summarizes questions and approaches to consider regarding certification systems' forest management standards. For example, are the standards performance and outcome-oriented, and do they require significant improvements in forest management beyond regulatory norms? How thoroughly do the standards protect and restore priority natural resources

and cultural values? Examples of such priorities include: managing for a full range of native tree species, vegetation, and habitats; prohibiting the conversion of natural forests to tree plantations and non-forest land uses; protecting Indigenous Peoples' traditional rights over lands and resources by securing their Free, Prior, Informed Consent (FPIC); and protecting rare and endangered ecosystems, including Intact Forest Landscapes (IFLs). Likewise, what is the system's "bottom line" for certification, as evidenced by certified forest management in indicative situations?

Finally, [Appendix IC](#) highlights questions and considerations regarding certification systems' audits and label claims. Examples include: whether audits are conducted by third-parties with a full range of environmental, social, and forestry expertise; mechanisms for transparency and accountability; the system's track record in addressing non-compliant certificates; and mechanisms to ensure that label claims are accurate and backed-up by CoC verification.

These topics and others covered in [Appendix I](#) are by no means complete lists of necessary elements for forest certification systems' institutions, procedures, and standards. For additional considerations, see the Credibility Principles and Codes of Best Practice of the ISEAL Alliance, [WWF \(2015\)](#), and the ISO CASCO standards. The FSC can also be considered a benchmark against which to evaluate other systems.

Other Current and Emerging Points of Interest

An important ongoing area of study is whether certification systems adequately protect forest ecosystems and biodiversity, or otherwise leverage significant improvements in forest management from environmental, social, and long-term sustainability perspectives. The subject of certification outcomes has received some attention in the context of FSC certification in the tropics. However, the topic has not received much attention in other regions, for example, North America and Europe—or with regard to other major forest certification systems.

An illustrative cross-section of the existing work on certification outcomes might include: [Newsom et al. \(2006\)](#), which used corrective action requests (CARs) as an indicator of management improvements stemming from certification. [Zimmerman and Kormos \(2012\)](#), which raised questions about the sustainability of reduced impact logging (RIL) practices. [Ebeling and Yasué \(2009\)](#), which looked at how contextual factors affect the ability of certification to improve forest management. [Romero et al. \(2017\)](#), which references and discusses many existing evaluations of FSC certification outcomes, and provides recommendations for evaluating certification outcomes in the tropics. And finally, [Sheil et al. \(2010\)](#), whose articles, case studies, and survey of experts provide perspectives on a number of topics, including biodiversity and certification in the tropics.

Deforestation continues to be a serious problem globally, leading some observers to question whether certification is effective at curbing outright forest loss. With some certification systems, the problem may lie partly with insufficient prohibitions on deforestation in their standards. However, with FSC certification, the issue is not the system's standards, which forbid significant conversion of natural forests to tree plantations, agriculture, and other non-forest conditions.

Rather, as [Sheil et al. \(2010\)](#) suggest, the challenge rests more with how only a portion of tropical forests (and others) are FSC certified, and with inherent limits in certification systems' ability to affect management in non-certified forests. This raises the question of whether the economic value of certification to forest owners and managers can be improved, to offset the opportunities they see in conversion and deforestation—and how often deforestation is driven by market trends that can be affected by certification systems, sustainable purchasing decisions, and increasing certification-related revenues for forest managers. Some parties that convert forests to agriculture, residential development, and other land uses in both developed and developing countries may simply not be interested in managing for forest products.

Of course, definitions and data can also factor into the deforestation picture. Conversion of natural forests to plantations and some non-forest uses can be missed by data based on definitions of "forest" that rely too simplistically on minimum canopy cover. Public and private sector initiatives might then be compromised, should they rely on such data and definitions. Short-term loss of forest cover due to timber harvest followed by tree planting or natural regeneration should also not be confused with deforestation (though it might still involve the conversion of natural forests to plantations).

Similar dynamics and questions are emerging in the debate over certification and Intact Forest Landscapes (IFLs) (i.e., mostly forested landscapes of at least 50,000 ha that have been minimally influenced by human activity, per [IF and GFW, 2006](#)). Unlike other systems, the FSC has implicitly, and now explicitly, prohibited degrading the majority of IFLs to non-IFL conditions. As with deforestation more generally, IFL loss continues to be a problem globally (see [Potapov et al., 2017](#)). Here too, forest managers' incentive to become certified may be outweighed by lucrative opportunities to remove timber from largely untouched "wilderness" forests, given that maintaining forests as IFLs inherently sets sharp limits on road construction, logging, and other industrial forestry operations. Thus some observers argue that it would be better to allow IFLs to be converted to managed but certified forests, than to see them impacted by even more intensive non-certified operations. Researchers looking at forest canopy closure in the tropics have also argued that careful road construction, timber harvest, and road closure practices can enable IFLs to return to IFL condition over time; see [Kleinschroth et al. \(2018\)](#), for example.

Meanwhile, many environmental NGOs point-out that IFLs represent some of the planet's last remaining intact wild ecosystems, and that their biodiversity, carbon storage, and other environmental and cultural values argue for more strict protection from industrial activities. Some research also suggests even the lightest-touch industrial forestry can result in significant harm to IFL values, regardless of canopy closure. [Morgan et al. \(2018\)](#), for example, found chimpanzees among the imperiled species impacted by selective logging of primary forests, including in certified forests. Perhaps not surprisingly, even [Kleinschroth et al. \(2018\)](#) suggest

that saving the world's last frontier forests may require enhanced protected area networks and other approaches beyond certification alone.

There is a difference, of course, between finding that certification alone is unlikely to solve all of the world's forestry related challenges, and suggesting that certification is unimportant or lacking in value. As long as deforestation, degradation of managed forest ecosystems, and social injustices continue to be of concern in the forest sector, consumers and businesses may continue to find value in avoiding products associated with those practices. Instead, they may wish to associate their brands with more environmentally and socially progressive forest management.

Questions regarding the circumstances for certification to be successful are also relevant beyond the tropics and other regions where IFLs and deforestation have received more attention. In the United States at least, it has been a challenge to establish price premiums for certified products, and to ensure that any premiums "trickle down" to the forest owners and managers who ultimately decide whether to certify their forests. Indeed, it remains to be seen whether consumers in the United States can be encouraged to focus on purchasing certified products, even at price parity. With market access being a principle factor in demand for certified forestry in such regions, the bigger question may be whether sustainable corporate purchasing programs will continue to give preference to leadership systems like the FSC, as public attention shifts to climate and other topics—and whether NGOs will continue to play a role in influencing those purchasing priorities.

While threats remain to some IFLs, old-growth forests, imperiled species' habitats, and other conservation priorities in regions like the United States and Europe, occurrences of these values are now rarer, making their protection less challenging, at least for leadership-oriented certification systems. In such regions, the greater challenge may lie with finding the ideal balance between ecological restoration and continued commercial forest management. It is not always easy to sustain and repair biodiversity in ecosystems impacted by generations of intensive management, while enabling forest managers to make reasonably competitive financial returns. With the FSC in the midst of updating its national/regional forest management standards, these are pertinent and timely questions.

The proper balance among environmental, social, and economic objectives can also depend on other contexts, such as land tenure. While the FSC's international standards (i.e., the FSC P&C and more recently adopted International Generic Indicators (FSC, 2018)) are intended to provide some global consistency across all forests, the system's use of regional/national Indicators to flesh-out and implement the P&C has long recognized that ecological, silvicultural, social, legal, and other contexts vary greatly among and within regions. To varying degrees, the SFI and some FSC regional/national standards also recognize that publicly owned forests may need to be managed for a different balance of objectives than private commercial timberlands. Many systems also recognize that less demanding and costly certification procedures are warranted for the smallest and least intensively managed forests. For example, those managed by some local communities, families, and other "smallholders" or non-industrial private forest owners. The FSC continues to explore new approaches, and might benefit from research on the approaches best suited for different regions and types of smallholders. The capacity and needs of smallholders in regions like the US and Europe will be quite different than in developing countries.

The condition of the surrounding forest landscape can also be an important contextual variable. The FSC's international standards recognize that when operating in landscapes with lower levels of ecosystem protection, for example, forest managers should do more to conserve and restore "representative sample areas" of fully functioning ecosystems in their management units. This includes management units that may be currently managed as plantations.

Another topic to watch is whether the FSC's new Ecosystem Services Procedure can enable greater levels of ecosystem protection and restoration to be economically feasible for forest managers. (The Procedure builds on lessons from the Forest Certification for Ecosystem Services Project.) An obvious and important opportunity is for governments, local communities, Indigenous Peoples, and other forest owners to secure financing to help expand protected areas networks and high carbon forests, water quality, and other ecosystem services. If successful, this could enable the FSC to help support forests where commercial management is not the primary goal. However, might the approach also potentially support more conservation oriented management of commercial forests?

Some systems are also exploring risk-based approaches to certification. Thus far, the quality and effectiveness of these approaches appears to vary widely. The FSC's long-standing recognition of the precautionary principle may represent the high-quality end of the spectrum, though it is unclear how consistently the principle is applied in practice. At the other end perhaps, lie approaches taken by forest-related systems like the Sustainable Biomass Partnership, where cursory regional data on forest trends is used in lieu of assessments of actual conditions in source forests (see NRDC and DA, 2017). The FSC's "Controlled Wood" system for minimizing the risk of controversial forest sources being included as non-certified content in product lines bearing the "Mix" label has also been of questionable efficacy, but is evolving and is more ambitious than competing systems' approaches.

The FSC's ongoing round of standards development also merits attention, as it is serving as an ad hoc testing ground for new approaches to risk. Updates to the FSC P&C in 2012 more explicitly provide for some certification requirements to be proportionate to differing contexts of "scale, intensity, and risk" (SIR). In turn, FSC (2016) outlines approaches for FSC national/regional indicators to codify those requirements. Put most simply, FSC (2016) encourages more thorough approaches to forest management (e.g., assessments, planning, monitoring) in higher risk contexts (e.g., larger-scale or more intensive forest management operations, or more vulnerable natural resources or cultural values). Conversely, more streamlined approaches are encouraged in lower risk contexts.

Certification systems are also being challenged to more effectively adopt and implement social justice promises. While the road has been bumpy at times (such as evidenced during debates at the 2017 GA), the FSC continues to lead with renewed commitments

to fully respecting the rights of Indigenous Peoples and communities to exercise FPIC over management affecting lands and resources to which they hold traditional rights. It remains to be seen whether other certification systems will follow suit—and how all systems will approach the topic in regions where FPIC implementation has received less emphasis to date. The same might be said for the FSC and other systems, with regard to commitments to respecting workers' rights and gender equity.

Some of these topics are likely to play out in new High Conservation Value (HCV) Frameworks. The 2012 updates to the FSC P&C (and further amendments in 2014) also clarified the system's definition of HCVs, including for IFLs and for the role of engagement with Indigenous Peoples and local communities during HCV identification. In 2015, the FSC called for national/regional standards to begin including HCV Frameworks, to provide nationally/regionally specific interpretations of, and management approaches for, the P&C's six HCV definitions. A template and guidance for Frameworks are now being finalized. These Frameworks are likely to build on existing HCV guidance, toolkits, and interpretations documents, including those already found in some national/regional standards, and those developed for some countries by the High Conservation Value Resource Network. However, this is also new territory in some regards, and input from environmental and social scientists and other experts may be timely.

Looking Down the Forest Road

Certification systems with more rigorous standards and higher expectations can face challenges not felt by systems that focus more on endorsing status quo forestry practices. Meeting leadership certification systems' higher standards for forest management and conservation can involve significant opportunity costs for forest managers, in addition to the transaction costs of the certification process. Meanwhile, as noted above, leadership systems like the FSC have found it difficult to provide participating forest managers with price premiums, and also face being undercut in the market by competing systems that demand far less change in forest management. Other pertinent challenges include fully addressing the rights of Indigenous Peoples, and finding the right balance in addressing environmental and social risks associated with the non-certified content of mixed-source products. Likewise, while growth in the FSC's membership and roles has been an indicator of success, it has also posed challenges for a system that values democratic, member-driven governance, which is not always the most efficient process.

Maintaining and enhancing carbon stores and sequestration in certified forests should arguably be a top priority for all certification systems, both as part of more comprehensive strategies to minimize catastrophic climate change, and because of synergies with goals for protecting remaining intact forests and other ecological and social values. However, this remains a topic where certification systems' forest industry members have largely stymied progress.

Emerging dialogues over "sustainable intensification" also raise interesting and difficult questions. Is it possible there are "cake and eat it too" solutions to the conflict between continued growth in demand for wood, paper, and other forest products, and the finite (and in fact, often shrinking) nature of the resource base of forest ecosystems (i.e., supply)? This conflict is all the more acute, given that many forest ecosystems may already be over-tapped from the perspectives of imperiled species, water resources, carbon budgets, climate change adaptation, and other values. If not, is there realistic hope for alternate solutions, such as improved utilization efficiency and reducing, or at least stabilizing, global demand for consumption of forest products?

Likewise, how should certification systems and other market and governmental institutions decide which forests should be managed for commercial forest products, and which should remain mostly wild and dedicated primarily to ecosystem conservation and traditional use by Indigenous Peoples and local communities? Unlike some other systems, the FSC at least attempts to answer these questions, in part by requiring conservation of IFLs, HCVs, and other priority environmental values, and by requiring consultation with Indigenous Peoples, local communities, conservation NGOs, and experts. Yet even the FSC is still, quite understandably, largely oriented to operating in managed forests. This was recently evidenced in the United States, when the FSC US' new standard for certification of National Forests fell dramatically short of environmental NGOs' expectations for a standard that would focus on the conservation and restoration of these public forests, given their role in the broader forest landscape.

At the end of the day, it seems likely that certification will continue to be an important part of the forest conservation and sustainable business landscape, and global trade in forest products. Likewise, greater attention to topics such as those mentioned above can surely help improve the scope and effectiveness of certification systems, and also help purchasers and others make informed choices between leadership systems and their competitors. At the same time, questions will surely remain about what even the best certification systems can reasonably be expected to achieve, and where additional initiatives will remain imperative, including stronger public policies and regulatory frameworks for the protection and restoration of forest ecosystems and forest carbon stocks.

Appendix I: Additional Considerations for Comparing and Evaluating Forest Certification Systems

A Factors and Questions Regarding the Systems' Institutions and Governance

- How the system was established. While certification systems evolve, they tend to do so incrementally, and understanding their origins can be informative, including with regard to their underlying mission and sense of identity. For example, was the system originally established more to recognize the best forestry practices, or status quo practices?
- How the system is governed. Is there a multi-stakeholder governing membership, inclusive of forest producers, retail forest products companies, smallholders, Indigenous Peoples, other traditional forest communities, labor advocacy NGOs,

environmental advocacy NGOs, independent scientists, etc.? How open is the membership? Who elects or appoints governing board members? How do these bodies balance input and decision-making among stakeholder groups? What are the system's main sources of funding?

- How the system's forest management standards and policies are developed. Are the standards written and approved by multi-stakeholder bodies, and if so, how representative are those bodies of a true diversity of interests? How responsive are the standards developers to input from public and stakeholder consultations?
- How transparent and accountable are the system's decision-making bodies and institutions, including to the system's members and to a broad diversity of stakeholders?
- The extent to which the system meets the requirements and best practices established for certification systems by ISO and ISEAL.
- The organizations that endorse and support the system, including NGOs and retail companies. Do they include leading advocacy organizations, expert institutions, other civil society groups, and brands with strong commitments to environmental and social values?

B Questions and Approaches Regarding Certification Systems' Forest Management Standards

- The extent to which the standards are performance and outcome-oriented. Do they merely require forest managers to have systems and plans in-place, or do they also require managers' plans and on-the-ground practices to achieve explicit and clear outcomes? Are the standards written in a manner that requires independent verification of compliance, including in areas such as legal compliance, and compliance with social standards?
- The management practices and in-the-forest outcomes required by the standards, for priority topics such as:
 - Prohibiting the replacement of natural forests by tree plantations that lack most natural forest structure and biological diversity, or by agriculture or other non-forest conditions and land uses.
 - Requiring that successive harvest of timber and other forest products not deplete resource stocking levels, and that management is also financially sustainable.
 - Prohibiting the use of genetically modified organisms within certified forests.
 - Protecting all rare, threatened, and endangered species and their habitats, including those designated at national and subnational levels.
 - Protecting rare and endangered ecosystems, including old growth forests in regions where they are now rare, and Intact Forest Landscapes (IFLs) (i.e., mostly forested landscapes of at least 50,000 ha that have been minimally influenced by human activity, per [IF and GFW \(2006\)](#)).
 - Setting-aside reserve areas, especially within larger forest management units.
 - Protecting and restoring (where needed) unstable slopes, streamside zones, stream structure, water quality, and other watershed functions.
 - Effectively limiting the use of the most toxic herbicides and pesticides, including by encouraging silvicultural practices that can reduce dependence on such chemicals.
 - Managing for a full range of native tree species, vegetation, and habitats, and other forest structure and composition.
 - Fully recognizing and protecting the rights and cultural and natural resources of Indigenous Peoples and traditional local communities (e.g., people who do not identify as Indigenous but have similar long-standing cultures and use claims), including by securing their Free, Prior, Informed Consent (FPIC) over management affecting lands and resources to which they hold traditional rights.
 - Ensuring that forest tenures and harvest licenses were legally issued, without corruption.
 - Fully respecting the rights of forest workers, including those established by the International Labor Organization (ILO).
 - Adequately surveying the forest and consulting stakeholders and experts, to identify resources and values needing protection or restoration.
- The extent to which the standards require performance beyond compliance with existing forestry, environmental, and social regulations.
- Non-conformances (NCs) (formerly known as corrective action requests (CARs)) flagged by CBs in certification assessments and reports, to address situations where forest management does not yet fully meet the certification system's forest management standards. Do the NCs—and the corrective actions adopted by forest managers—indicate that the standards leverage significant improvements in forest management? Does a lack of NCs suggest the system tends to certify status-quo forestry, or forest operations that are already exemplary? (Note that NCs is the terminology used by FSC; other systems may use different terminology.)
- The condition of certified forests and how they are managed in regard to priority topics. What is the system's "bottom line" for certification, as evidenced by the most intensive forestry practices that are certified, and/or by certified management in regions where past management has severely impacted ecosystems, where native biodiversity and other values remain relatively intact and thus vulnerable, and/or where higher levels of social controversy exist? Are more degraded forests being restored to improved conditions? Are past violations of land tenure rights or other social injustices being redressed?

C Questions and Considerations Regarding the Systems' Certification Audits and Label Claims

- Whether certification audits must be conducted by independent, third-party CBs and auditors with a full range of environmental, social, and forestry science expertise. Do CB accreditation and audit procedures meet the best practices established by ISEAL?
- The extent to which the certification auditing process requires comprehensive stakeholder notification and consultation.
- The extent to which audit reports are made public and contain information sufficient to enable stakeholders to understand how the certified forests are managed, and what NCs have been issued to improve their management.
- The system's track record in addressing complaints filed against certificates for forests alleged to not be in compliance with the system's standards. What proportion of complaints result in corrections to the certificate, or the complainants otherwise feeling their concerns were addressed? Is the complaints system reasonably open and accessible to begin with, including per the best practices of ISEAL?
- The system's procedures for minimizing the risk of environmentally and socially controversial sources being included in the non-certified content of mixed-source products, that is, products not entirely from certified forests. How comprehensive and performance-oriented are these requirements?
- The extent to which label claims for mixed-content products must be proportionate to the products' inputs from certified forests, for example, via explicit indications of the percentage of certified inputs, or by limiting the application of labels to that percentage of product.
- Whether CoC verification is required for all products bearing the system's labels.

Acknowledgments

My sincere thanks for the insights and time of the many colleagues and experts who suggested topics or reviewed drafts of this paper, in particular Dr. Robert Hrubec and Dr. Marion Karmann, who both provided significant contributions.

Abstract

Ecosystem services (ESs) is the concept and term used to represent the benefits that people obtain from an ecosystem. No ideal system for identifying and classifying ESs has emerged, but the scheme developed by the Millennium Ecosystem Assessment (MEA, 2005) is used extensively. Investigations of ESs help provide the basis for measuring the benefits individuals, families, businesses, communities, and the global society receive from forests; for weighing the increases and decreases in benefits from actions that alter the forest; and for describing the disparate effects on different groups affected by the actions. Most forests are managed to emphasize the production of logs, fuel wood, and other goods readily exchanged for cash through market transactions. This emphasis diminishes forests' ability to provide nonmarket benefits, such as mitigating climate change by sequestering atmospheric carbon dioxide and sustaining indigenous cultures and lifestyles. The value of the forgone benefits can exceed the value of the commercial products derived from forests. Detailed studies in the Pacific Northwest of the U.S. demonstrate that the loss can exceed the value of commercial log production by, perhaps, more than 80-to-1. Proposals for reducing the harm from the production of commercial products include paying forest managers to produce nonmarket benefits and punishing them for not doing so.

Ecosystem Services From Forest Biomes

By recognizing that ecosystems provide specific benefits to people, MEA (2005) provides a useful framework for understanding the many ways in which ecosystems are important, both positively and negatively, to individuals, families, businesses, communities, and the global society. It also provides a foundation for measuring the socioeconomic value of ecosystems in terms similar to those used to measure the value of goods and services produced by human activities. This information can provide the basis for quantitatively determining if actions, such as logging or habitat restoration, that alter an ecosystem, will yield net benefits or net costs for different groups and for society as a whole.

MEA (2005) aggregated ESs into four categories:

1. Provisioning services, which involve the production of materials or energy useful to humans in the form of food, water, building materials, and fuel wood.
2. Regulating services, which benefit humans by regulating the characteristics of the environment that affect human wellbeing. These services influence the quality of air, soil, water; remove carbon dioxide from the atmosphere; moderate floods; filter waste products from streams; control pests and vector-borne diseases.
3. Cultural services, which provide humans with opportunities for ecosystem-based spiritual experiences and sense of place; inspiration for culture, art, and design; attractions for recreation and tourism; enhancement of mental and physical health.
4. Supporting services, which lay a foundation for the three other categories of services through habitats for plants and animals, and genetic diversity.

The MEA's chapter on "Forest and Woodland Systems" (Shvidenko et al., 2005) aggregated the ESs provided by forest biomes into 14 categories (Fig. 1).

The MEA's four-category classification system is widely accepted and used, but it has weaknesses as well as strengths. The strengths include recognition that some ESs influence the quantity and quality of *goods* derived from forests, while others influence the quantity and quality of *experiences* people have when they interact with forests. Forest ecosystems, for example, can influence the amount, timing, location, and temperature of water in streams. They also can provide opportunities for participating in outdoor recreational activities, reinforcing spiritual beliefs, sustaining a culture, and enjoying aesthetically pleasing scenery. Applications

Category	Category
Biodiversity	Sports fishing/hunting
Climate regulation	Recreation

Fuel wood	Nonwood forest products

Fig. 1 Major categories of forest ecosystem services identified by the Millennium Ecosystem Assessment. Shvidenko, A., Barber, C. V., Persson, R. et al. (2005). *Forest and woodland systems*. Millennium Ecosystem Assessment; From Figure 21.6 Major Classes of Forest Services, p. 601.

of the MEA's framework have facilitated the compilation of information about the individual ESs themselves, i.e., the actual benefits the specific groups of humans derive from ecosystems, as well as the structures, processes, and functions that produce them. This work has clarified both the ability of existing research methods to identify, quantify, and socioeconomic importance of some ESs, and the limitations in their ability to describe others. Investigations into ESs, based on the MEA's framework, also have provided insights into the human activities that enhance or diminish the quantity, quality, and value of different ESs.

Experience using the MEA's framework has revealed two major weaknesses (Binder et al., 2017). One stems from unevenness in the data regarding the four categories of ESs. Provisioning services often involve the production and consumption of goods, e.g., logs and fuel wood, that are traded in market transactions. These transactions can provide voluminous data on the good's location and quantity, quality and value, and sellers and buyers. Market data also are available to describe many regulating services. For example, prices for houses in a floodplain might decline, relative to prices of comparable housing elsewhere, following an announcement to log an upstream forest and thereby diminish the forest's ability to regulate runoff and reduce downstream peak streamflows. In contrast, an ecosystem's cultural and supporting services typically are more removed from market transactions. Moreover, some of them, such as those associated with the role a forest plays in sustaining the culture of an indigenous group, are generally incompatible with market concepts.

The disparity in descriptive information and valuation data often has resulted in studies that focus primarily on the socioeconomic importance of market-oriented provisioning and regulating services (Zhang and Stenger, 2014). Such efforts can induce decision-makers and the public to conclude that the greater volume of data for market-oriented services means that these services are the only ones that exist or that they are more important than those that are not traded in markets and for which the data are limited. These beliefs then can lead to biased forest-management decisions that favor the production of market goods and disfavor the forest's ability to provide cultural benefits to indigenous and other groups, even when these, in truth, have greater value.

Another weakness in the MEA's framework stems from its lack of clarity about what is and is not an ES. Some have used it to focus on the immediate circumstances where people realize a benefit, e.g., when they log a tree, remove water from a stream, or hike a forested trail. Others have looked away from those events to focus on the ecosystem structures and processes that underlie them. This ambiguity is confusing and it can lead to a double-counting of ESs that shows a forest producing benefits for people once, when circumstances enable people to realize them and again when ecosystem processes create those circumstances.

In one significant effort to overcome the ambiguity (Boyd and Banzhaf, 2006), many economists have sought to refine the definition of an ES so that it includes only the components of nature that people directly enjoy, consume, or use to enhance their wellbeing. This approach has several key features. It focuses on the direct interaction with a component of an ecosystem that produces a benefit for people, not on the underlying ecosystem processes. Thus, it parallels the accounting economists use to measure the benefits consumers realize when they enjoy, consume, or use goods and services produced by human systems. It recognizes that, in most cases, people derive benefit not from an ecosystem in isolation but through interactions between the ecosystem and human-produced goods and services. For example, people don't realize a benefit from a forest's production of timber and fuel wood until workers, using tools, cut trees down. When such an interactive process is necessary to realize benefits from an ecosystem, then the ecosystem service is responsible for just a component of the benefit, not all of it.

This refined definition of ESs also recognizes that the direct enjoyment, consumption, or use of a component of nature can occur through vastly different activities at various scales, involving individuals, families, business and other organizations, communities, and society as a whole. People realize benefits from a forest's timber-production ESs embodied in trees having the size, location, and quality characteristics that can be converted into merchantable logs. The benefit from these ESs accrue to a single entity: the commercial enterprise that employs labor and machines to convert the trees into logs and then uses the logs as an input to its production processes. Recreational ESs lie latent until people enter the forest for hiking, biking, etc. Multiple people can realize the recreational benefits without extracting goods from the forest. The benefits from climate-related ESs materialize outside the forest, when forest growth sequesters and stores atmospheric carbon dioxide, thereby enabling individuals, businesses, and communities around the world to enjoy a reduction in climate-related risks. The benefits from ecosystem-existence ESs similarly manifest themselves without direct interactions with the forest, as individuals derive enjoyment from knowing that forest structures, processes, and species currently exist, with the prospect of passing these features to future generations.

A forest can produce many distinct streamflow-related ESs that accrue to different groups, within and downstream from the forest. For example, the forest might convey benefits to:

- Downstream farmers, as they use water the forest delivered to the stream in amounts and at times useful for irrigating crops.
- Downstream municipal/industrial consumers, as they use water the forest delivered to the stream in suitable amounts and with appropriate quality characteristics (e.g., favorable turbidity and unharmed compounds).
- Downstream communities, as they enjoy reduced flooding because the forest regulated water runoff and diminished peak flood flows.
- Subsistence, commercial, and recreational fishers, as they seek to catch fish that are in the stream because the forest provides suitable habitat.
- Educators and students, as they observe and study fish that migrate between forest and downstream habitats.
- Water-sports enthusiasts, as they enjoy in-forest and downstream streamflows in amounts and with quality characteristics suitable for kayaking, rafting, etc.

These examples suggest the broad diversity of ESs that can directly provide benefits to people living nearby and to those living far away. Some of the ESs, such as those associated with reducing climate-related risks, manifest themselves as people enjoy benefits directly from components of the forest ecosystem, but without direct physical interaction with the forest. Others, such as those associated with timber production and recreational hiking, do not exist without direct activity of people in the forest. Many ESs embodied in a forest's influence on streamflow become manifest through a direct interaction with a component of the natural environment but outside the forest's borders.

The focus on the direct enjoyment, consumption, or use of a component of the ecosystem is useful for economic analyses that seek to quantify the value of ESs in monetary terms. It is less useful for those concerned with ESs that don't fit with monetization, either conceptually or empirically or both. To fill this gap, the Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services (IPBES) has developed a different approach for defining and weighing ESs (Diaz et al., 2018). Although it does not overcome limitations in the data available for measuring some ESs, it places greater emphasis on nonmarket services. It also emphasizes using perspectives, such as those of indigenous peoples, that can complement market data regarding the definition of the services themselves, the interactions between natural and social systems that govern the delivery of these services, and the multiple ways in which the services contribute to human wellbeing. The IPBES has identified 18 distinct ESs (Fig. 2). This approach is new and it remains to be seen how well it boosts future understanding on ESs, monetary as well as nonmonetary.

Other categorization systems focus more narrowly, recognizing the tension between market-oriented and nonmarket ESs. These often look first at ESs associated with extractive activities, distinguishing between those that produce timber and those that produce bushmeat, fruits, nuts, livestock fodder, and other products. They then consider nonextractive ESs. Some of these are associated with specific benefits to people, e.g., removal and storage of atmospheric carbon dioxide to mitigate climate-related risks, and streamflows suitable for irrigation or municipal/industrial uses and without peak flows that threaten high flood damage. Others are associated with sustaining forest structures, processes, and species perceived to have existence or bequest value, or to be necessary for preserving a forest's ability to produce extractive products in the future.

Economic Values

Willingness to Pay and Willingness to Accept

Any effort to measure the socioeconomic importance of forest ESs should make clear the perspective from which the measurement is taking place. Economists typically employ one or both of two perspectives. One considers value from the perspective of a buyer's

Category	Category

willingness to pay (WTP) for something she does not already possess. The other looks at what a seller is willing to accept (WTA) as compensation to relinquish something she already possesses. In some market settings, with many fully-informed buyers and sellers making small transactions, the two perspectives likely yield identical estimates of the value of the good or service being traded. These conditions, however, are unlikely to exist when estimating the value of most ESs. As a result, the two perspectives can yield very different values.

Differences most often arise because the WTP values depend on the potential buyer's ability to pay, i.e., his accumulated amount of money. This perspective, thus, is biased against those who are poor. For example, if two communities, one rich and one poor, compete for a forest component, the WTP perspective would favor the richer community because it has a greater ability to pay, even if, in truth, the poorer community would realize a greater benefit if it won the competition.

Additional differences arise because, in general, people require more compensation to relinquish something than they are willing to pay to acquire the same thing. The difference may be small for a market-traded good or service that exists in substantial quantity and for which there exist substitute goods or services. With a nonmarket good or service closely associated with a community's spiritual or cultural identity, or with its beliefs in what is right or wrong, then the WTA perspective of value may far exceed the WTP perspective of value. In some circumstances, a community may conclude that no amount would adequately compensate them for relinquishing a good or service. These circumstances can readily arise when a commercial entity seeks to displace an indigenous community from lands or waters it has long occupied. Using the WTP perspective to estimate the value of the community's loss could starkly under state the true harm members of the community would experience.

Despite the significance of the distinctions between WTP and WTA perspectives of the value of ESs, most available data on value represent the former. Those who use these data should remain aware of the potential for bias in situations where WTA would more appropriately represent the value people place on ESs when faced with losing them.

Estimates of Value

Numerous efforts have sought to quantify and estimate the value of particular ESs from a particular forest biome (Costanza et al., 2017). These efforts contributed to Costanza et al. (2014), which summarized the relevant literature to estimate the global average value (US\$, 2007) of ESs provided in 2011 by different biomes. The estimates for tropical and temperate/boreal forests were \$5382 and \$3137 per hectare per year, respectively. These estimates build on an earlier attempt, Costanza et al. (1997) to quantify the global economic value of ESs throughout the world. The results from that earlier effort show the distribution of value generated by different types of ESs (Fig. 3), with nutrient cycling and climate regulation accounting for more than half of the total. The percentages shown should be considered extremely rough estimates, but they nonetheless provide a general sense of perceptions at that time about the relative importance of different forest ESs.

Siikamäki et al. (2015) estimated, for each country, the value of nonwood ESs from forest biomes. The estimates update values used by the World Bank to describe the total value of each country's forest resources and to evaluate the benefits and costs associated with actions that alter the area or productivity of forest resources. The researchers found (Fig. 4) that, across the globe, ESs associated with recreation, habitat and species protection, nonwood forest products, and water produce benefits worth US\$95 per hectare per year (2013 U.S. dollars). Regional values range from US\$13 (Sub-Saharan Africa) to US\$156 (East Asia & Pacific). The researchers also estimated the present value, a single amount today that is the sum of annual benefits expected over the next 25 years, and each annual value discounted 4% per year in the future. The present value can be useful for comparing the value of nonwood forest ESs against the present value of the wood products that would be produced by managing the forest with that emphasis over the same period.

Tradeoffs

Many, perhaps most, economic assessments in recent years of forest ESs have focused on the tradeoffs associated with the production of wood products. Many assessments look beyond the nonwood forest products included in Fig. 4 to focus on the ability of living trees to mitigate the effects of human-caused changes in climate [including other changes, such as in ocean acidification] by removing carbon dioxide from the atmosphere, through photosynthesis. Unlogged forests also can store carbon in living and dead matter on the forest floor and in forest soils. Logging accelerates the release back into the atmosphere of some of the carbon stored in the forest. It also stops the trees from continuing to remove more carbon dioxide from the atmosphere in the future and, although the growth of smaller replacement trees can offset some of the forgone sequestration, it can take years, decades, even centuries, for total offset to occur if at all given most logging is on short rotation intervals. In the meantime, the additional forest carbon in the atmosphere will contribute to intensification of climate change.

Few studies have directly compared the value of the benefits humans realize from the fiber/fuel ESs that manifest themselves when trees are killed against the value of the climate-mitigation ESs realized when trees are left in the forest. Measuring the value of the fiber/fuel ESs involves using market data on "stumpage value," i.e., the value of trees just before they are logged, which isolates the value of the ESs associated with the forest's production of wood fiber from the value of human-provided services that kill the trees, process them, and convey logs and fuel wood to market.

Social Cost of Carbon

Measuring the value of the climate-mitigation ESs of forests left unlogged involves estimating the social cost of carbon dioxide (SC-CO₂). This variable represents the net global economic damage expected to result from a 1-ton increase in atmospheric carbon dioxide or, alternatively, the damage that would be avoided by removing the same amount from the atmosphere.

One of the most thorough comparisons of fiber/fuel ESs and climate-mitigation ESs comes from calculations by the U.S. Bureau of Land Management (BLM) for forestlands it manages in western Oregon, in America's Pacific Northwest. These forests are among the best in the world for their ability to sequester carbon and produce wood fiber, and market data suggest that, if dedicated to timber production, these lands would command prices exceeding US\$12,000 per hectare. Recognizing the high productivity, the

BLM's analysis provided calculations for several alternatives that show the stumpage value of trees that would be logged annually and the SC-CO₂ of trees that would be left standing. Comparing alternatives with more logging against others with less reveals the tradeoffs between timber-production ESs and climate-mitigation ESs. The comparisons show that, for alternatives that increase logging, the value of the global damage resulting from the associated carbon dioxide emissions would exceed the stumpage-value of the logs by >4-to-1.

This ratio reflects 2013 research that estimated the SC-CO₂ to be about US\$40–50 per metric ton of carbon dioxide emitted over the next few years. Subsequent research (Ricke et al., 2018) revised the estimate upward, to more than \$400 per ton carbon dioxide, with \$800 per ton as the upper bound of potential outcomes. Hence, the new research suggests that the climate-mitigation ESs provided by these forests exceed the fiber ESs by at least 30-to-1 and, perhaps, by >80-to-1. The actual ratio likely would be even higher, insofar as these estimates of the SC-CO₂ represent only a subset of damages resulting from carbon dioxide emissions and exclude others, such as those associated with all the potential economic harm from ocean acidification.

These numbers strongly suggest that logging less, rather than more, of these forests would result in a higher level of wellbeing for global society. They do not, however, definitively show that halting all logging across all of the forestlands managed by BLM is warranted. The values for climate-mitigation ESs and fiber ESs reflect the averages for the entire area. Spatially specific data likely would show a lower ratio for some hectares and a higher ratio for others. It is possible that a reverse ratio, i.e., showing log value exceeding climate-mitigation value, might obtain for lands with trees capable of producing high-value lumber and proximate to a lumber mill with the productive capacity to do just that.

Other Ecosystem Benefits

Other research in the Pacific Northwest illustrates the range of values for ESs other than those associated with timber production and mitigation of climate risks. Most of these are tradeoffs for timber production and cobenefits for climate-risk mitigation. Unlogged forests, for example, can increase streamflows during arid summer months, because mature forests typically consume less water than do younger trees that are planted after logging. In addition, mature trees have greater ability to condense fog, which drips to the ground, soaks into the soil, eventually leaks into streams, and becomes available to irrigators and municipal/industrial users during dry months. In some locations, these processes can increase the amount of water reaching the soil by about 0.5 m. Limited information from transactions involving streamflows suggest that the increased annual streamflow produced by the ESs of unlogged forests can exceed US\$125 per hectare.

Federal forests of the Pacific Northwest are notable in part because of decisions in the 1990s to reduce logging markedly in response to research showing that continued logging would seriously jeopardize the continued existence of species dependent on unlogged forests. Attention focused on one species, the Northern Spotted Owl (*Strix occidentalis caurina*), and the change in forest management afforded economists with an opportunity to measure the public's preference for protecting this species and its habitat relative to the market value of the timber that would be produced if the lands were logged. Economists (Hagen et al., 1992) carefully surveyed U.S. households to ascertain their average willingness to pay for the continued protection of owls and the old-growth forests that provide them habitat. This amount, multiplied times the total number of U.S. households, provides an estimate of the overall benefits of protecting old-growth forests and owls.

The economists recognized that these results required further validation because most people have little experience with expressing their willingness to pay to protect a species and its habitat. Hence, they might not fully comprehend that protecting the owls and their habitat would come at considerable cost, through the reductions in the supply of and higher prices for lumber and other wood products that would accompany the constraints on logging necessary to provide the protections. To verify that survey respondents understood the consequences of expressing what they would be willing to pay, they researchers asked them to compare this amount against the value of the forgone timber. Under varying analytical assumptions, they found that survey respondents perceived that the ratio of benefits to costs for sustaining the forests' old-growth habitat ESs for owls ranged from 3.5 to 42.6. This finding is consistent with similar analyses of the benefits and costs of protecting other rare, threatened, or endangered species. A 1996 review of 20 studies of the economic value Americans place on such species found that the costs per household of protecting endangered and threatened species fall "well below" the benefits. A 2009 update of the review (Richardson and Loomis, 2009) found that Americans' valuation of threatened and endangered species has increased over time.

Synthesis of the economic studies of the value of diverse ESs produced by federal forests in the Pacific Northwest provides insights into the overall importance of benefits derived from forest products relative to other benefits. Economists from the U.S. Forest Service (Haynes and Horne, 1997) found that, for forests managed by that agency in the state of Washington, the value of timber production represented <8% of the total value of ESs in 1995, and they predicted this value would fall to <2% by 2045. The value of camping, fishing, and other recreational benefits, in contrast comprised >30% of the total value in 1997, with expectations that this would grow to >60% by 2045. Values associated with the ability of unroaded areas to sustain the existence of structures, processes, and species associated with native forests accounted for almost 60% of the total value in 1997 and almost 35% of the expected total value in 2045.

Payments for Ecosystem Services

Emphasis on Extractive Products

Management of the world's forests generally emphasizes ESs associated with the extractive products. [Marta-Pedroso et al. \(2014\)](#) reports that more than one-half of the world's forestlands are managed to capture value from a specific, narrow set of ESs: 30% focus on provisioning ESs associated with the production of wood, fiber, biomass, and nonwood forest products, 11.5% on conserving biodiversity, 8.2% on conservation of regulating services, and 3.7% on recreation, education, cultural heritage and other social services. Another 22.6% of forestlands are managed with a different specific focus, lack a focus, or have a focus that could not be classified. The remaining 24% are managed for multiple uses to capture value from a broader set of ESs.

The emphasis on managing forests to produce extractive products rather than nonmarket ESs reflects market realities. Many forest managers want to generate cash income from the sale of market-oriented goods and services, such as logs and fuel wood. Over time, these actions have diminished the productivity of ESs associated with nonmarket goods and services. This shift favoring market goods and services can occur even when their value is less than the value of the lost nonmarket goods and services, so that the total value of all ESs diminishes. Historically, a common approach for arresting or avoiding such outcomes has entailed placing prohibitions on logging and other activities in protected areas. This approach often proves ineffective, however, because enforcing the prohibitions can become expensive and subject to corruption.

Payments for Nonmarket ESs

Over the past several decades, another approach has evolved ([United Nations Development Programme, 2018](#)). It involves providing forest managers with cash or other incentives to sustain a forest's ability to produce nonmarket ESs. These incentives, commonly called payments for ecosystem services (PES) can take several different forms. For example, a national government might provide tax subsidies to forest landowners that help conserve water quality in streams by not logging trees in riparian zones. A downstream community vulnerable to flooding might seek to reduce peak flood flows by paying an upstream community to not log trees that intercept and slow the runoff from storms. A corporation seeking to develop expensive homes on a parcel of land might pay the owner of adjacent forestland to forgo logging of trees that will increase home prices by providing an aesthetically pleasing view. A conservation group might provide cash income, health services, and other assistance to induce an indigenous to help prevent outsiders from logging trees illegally.

The PES approach generally seeks to reshape powerful market forces so that they encourage the production of diverse ESs. When successful, it creates a new market. In this market, landowners and forest managers sell services that produce clean water, reduce peak floods, attractive views, etc., and entities that see the value of these things become buyers. In concept, these new markets should work as effectively and efficiently as the markets that govern selling and buying of countless goods and services every day. In practice, though, efforts to establish these markets often fall short. They often have difficulty defining what is being bought and sold. Many ESs are hard to define and measure precisely, making it difficult to develop a sound seller-buyer contract and, once executed, to determine that all parties are living up to its terms. Evolving science likely will diminish these difficulties over time, but it will not address another problem. PES proposals often encounter broad resistance because they seek to replace the polluter-pays-principle, a socio-political structure in which a polluter must pay society for degrading ESs, with the beneficiary-pays-principle, in which society pays a landowner not to degrade the ESs. Those who resist PES proposals might see opportunities to use the evolving science in litigation aimed at broadening the application of the polluter-pays-principle to punish landowners that harm society by degrading nonmarket ESs.

Conclusion

Forests provide many benefits to people throughout the world, but they cannot produce all types of benefits to all the people all of the time. Activities that emphasize the production of some benefits for some groups can diminish a forest's ability to produce other benefits for other groups. Many forests now produce a narrower set of benefits than in the past, with an emphasis on the production of logs, fuel wood, and other market-oriented goods. This emphasis yields direct socioeconomic benefits for commercial entities that use these products, but harms those who no longer can realize benefits from the enjoyment, consumption, or use of components of the forest that are displaced by the commercial production. Careful research, especially in the Pacific Northwest of the U.S., demonstrates that the overall harm to society can outweigh the value of the logs produced by industrial timber operations.

The widespread emphasis on extracting commercial products from forests occurs because these products can readily be converted into cash through market transactions. Efforts are underway to develop similar opportunities for forest managers to receive cash for producing benefits that currently are not traded in markets, through processes that generally receive the label, payments for ecosystem services. The establishment of such payments has been slowed, though, by technical difficulties in ensuring that forest managers satisfy contractual obligations to deliver the specific services and by philosophical opposition to paying managers when they produce these services rather than punishing them when they don't. Anticipated improvements in the ability to measure the impacts of management activities on a forest's ability to produce various services, and to measure the harm resulting from the diminution of noncommercial benefits, may promote both efforts to pay managers to produce these benefits and efforts to punish those who don't.

Abstract

The Mekong region (Cambodia, Laos, Myanmar, Thailand, Vietnam) forms the majority of the Indo-Burma Biodiversity Hotspot, one of Earth's richest, most diverse terrestrial biomes. Its forests and wildlife survived various modern conflicts and for centuries enabled traditional peoples to live from their bounty. Since 2000, more than 12 Mha has been lost, and some 1.3 Mha of the most valuable forest ecosystems are now being destroyed each year. (In 2018 an additional ~1 Mha was destroyed.) As Earth faces mounting pressure from global warming, forest habitats, wildlife and biodiversity in the Mekong are being rapidly destroyed by industrial-scale illegal logging that precedes agricultural expansion for export commodities, made possible by uncontrolled timber trafficking and exports. Current prospects for improvements in forest governance and biodiversity conservation are dim, given authoritarian governments, institutionalized corruption at all levels and lack of space and safety for genuine civil society participation.

Introduction—Historical and Cultural Context

Scenes from Stanley Kubrick's 'Apocalypse Now' brought to the world, a visceral impression of the dense tropical forests in which lived many upland tribal peoples. Until then sporadic TV coverage depicted forests engulfed in flames as incendiary bombs blasted the landscapes, marking perhaps the beginning of serious destruction of old-growth forest ecosystems that occupied over half the Mekong region's land area only half a century ago.

Forests are deeply woven into everyday regional cultural and spiritual beliefs—from upland animists to lowland Buddhists, even for those now living in large urban areas—and play a special, often sacred role in their lives. Almost all rural villages in the region have sacred forest groves and temples. Widening forest destruction, including logging sacred forests, results in enduring cultural, spiritual and economic suffering, especially for traditional communities. It is not possible here to explore the manifold effects of forest destruction and biodiversity loss on the millions of people who once lived in the region's forests. These include widespread loss of lineages, cultures and languages, effects on gender roles, loss of livelihood resources and dispossession.

Post-WWII newly independent national governments claimed responsibility for enacting and enforcing laws governing allocation of land and how it is used. They asserted ownership and control of almost all forested land, classifying it for production, protection or conservation; the latter including national parks and biodiversity protected areas.

Over the last two decades over 12 million hectares (Mha) of forests, the majority dense or primary forests, in the region has been destroyed, a historic and continuing failure of governments to protect what is considered to be national heritage and a public good. Ever expanding forest destruction has resulted in impoverishment of thousands of forest-dwelling ethnic groups, theft of their lands, livelihoods and heritage, including their skills as forest managers.

Until about two decades ago forest destruction was, arguably, mainly driven by agricultural expansion to feed growing populations. But in the last two decades the scale and rate of forest destruction has far outstripped meeting regional needs, partly due to slowing population growth, even after taking into account rising affluence. In brief, governments have presided over the destruction of their nations' natural heritage, all too often for personal gain.

This study commences with an assertion that the main threat to regional forest ecosystems is illegal logging, to which must be added massive illegal trafficking in unprocessed wood. Approximately half of the wood exported from the region is unprocessed logs and sawnwood, which according to existing regional export bans is illegal. Approximately 90% of this is imported by Chinese businesses, and officially documented by Chinese customs authorities.

This conclusion parallels Eyster's (2019) in 'Last Days of the Mighty Mekong'—published just after this chapter was drafted. Conserving the Mekong's riparian ecosystems and cultures, as with Mekong's forest ecosystems, depends on China ceasing its practice of increasingly exploiting its neighbor's natural heritage for its own economic benefit.

If Chinese companies were prevented from importing massive amounts of wood from old-growth forests, the reduction in demand would about halve the area being logged annually in the Mekong region. This would reduce regional forest destruction to about the level it was in 2008, before China became dominant importer of unprocessed wood from the Mekong's ancient forests.

The Mekong Region

The Mekong region (1.9 M km²) covers the majority and core of the Indo-Burma Biodiversity Hotspot (Mittermeier et al., 2004), with four forest biomes: tropical and subtropical coniferous, dry broadleaf forests, and moist broadleaf forests, and mangrove forests. The quality of Mekong forest ecosystems and species diversity were key criteria in nominating the region as a globally important Biodiversity Hotspot.

The Indo-Burma Hotspot (Fig. 1) includes all of Cambodia, Laos and Myanmar (Burma), and nearly all Thailand and Vietnam, plus parts of eastern Bangladesh, northeast India and southeastern China. Cambodia, Laos, Myanmar, Thailand and Vietnam form the majority of the hotspot. For several reasons these are grouped as the 'Mekong region.' The Mekong River watershed (0.9 M km²) encompasses over a third of the overall area.

The forests, rivers, wetlands, and limestone karsts are habitat for some 7000 endemic plant and 1048 animal species. As of 2019 there were approximately 2000 threatened species in the Mekong region: 250 mammals, 230 birds, 186 reptiles, 70 amphibians, 349 fishes and 554 plant species (IUCN, 2019).

The Mekong River connects all five countries; forests are logged, forest products traded (wood, wildlife, plants), poached and smuggled by people from all five countries (and others). Forest destruction in one affects biodiversity downstream and in neighboring countries. The region's national borders remain 'porous' for people and goods and even more porous and interconnected with regard to natural stocks and flows.

Mekong Forest History

This study focuses on forest cover changes in the Mekong Region in the 21st Century. At the beginning of the 20th century a range of estimates suggests that dense moist and dry tropical, dry upland, flooded and mangrove forests—covered about 90% of the ~2M km² regional landscape—about 66 Mha of lowland and 102 Mha of upland forests. In the uplands above 300 m (55% of the region) forest cover may have been as high as 95% until the early 1900s (Robichaud et al., 2009).

It is relevant to note environmental and social impacts of the French (1946–54), and American (1954–75) wars in Indochina—widespread bombing, defoliation and forced resettlement severely disrupted forest ecologies, traditional swidden and forest management practices in Vietnam, Cambodia and Laos. After the wars, governments in the region embarked on implementing 'forest conversion' with the purpose of converting forest resources and land into capital (Peluso et al., 1995), to be exploited for profit, often by outsiders.

Fig. 1 The Indo-Burma Hotspot. Notes: Green = protected areas (IUCN I-VI & NA), red areas = urban, yellow-brown areas = agriculture (0–100%), red lines = road network. From Weller, J.W., Hoch, C. and Huang, C. (2017) Atlas for the end of the world, <http://atlas-for-the-end-of-the-world.com>.

Using Thailand as an example, tropical wet and dry forests (38 and 51 Mha respectively) covered approximately 75% of the landscape in 1913. This declined to about 30 Mha by the late 1950s, and only 20 Mha remained by 1974 (Delang, 2006). By the 1970s almost all of dipterocarp and dry evergreen forests on Thailand's vast Korat plateau had been replaced by a mosaic of irrigated and rainfed rice fields, plus maize, soy and sugar (Rambo, 2017). The Khorat Plateau, the large 'white' area in central Thailand in Figs. 1 and 3 was historically mixed seasonal forest ecosystems (White, 1995) with significant populations of elephants and tigers.

Since the 1970s the Mekong region has lost one-third of its forests and, based on current trends, it is likely to lose another third by around 2030 (Carroll, 2018). Since 2001, destruction of 8 Mha of dense forests (> 75% canopy) and the flora and fauna within them, has substantially increased overall biodiversity threat levels.

Forest destruction since then, primarily for commercial agriculture expansion, but also uncontrolled industrial and illegal logging, hydropower dam construction and mining, has greatly reduced old-growth forests that covered most of the land for about 10,000 years. The last 20 years have seen the rate of forest destruction in all five countries accelerate. Over 2014–18, destruction of forests with > 30% canopy cover amounted to 5.9 Mha. Current indicators point to the likelihood this will continue or increase in years ahead.

Fig. 2 Mekong region forest quality by percentage of canopy cover (2000). From GFW 2018: <http://earthenginepartners.appspot.com/science-2013-global-forest>. Accessed through GFW on 09Nov18. www.globalforestwatch.org.

Fig. 3 Mekong region—forest destroyed 2000–17. Based on GFW 09Nov18. Notes: Areas with red stipple indicate forest cover (>30% canopy) lost over 2000–17; color intensity indicates greater total quantity of forest cover loss.

All five nations of the Mekong region are currently ruled by authoritarian/quasi-military governments, descendants of anti-colonial struggles. After 1975, new roads and technology enabled governments to extend their control to forested uplands populated by traditional ethnic communities. Closer state control and centrally dictated forest land zoning provided the means by which forests could be claimed as ‘state land’ and then logged.

Nominally logging requires permission, official or unofficial, from government agencies, traditional forest dwelling communities have no role or authority in this process. Authoritarian/military governments severely limit the rights and opportunities for citizens to oppose public and private ‘development’ projects likely to affect them ([Global Witness, 2013](#); [Transparency International, 2018](#)).

As a result, hundreds of thousands of people have been and continue to be forced from their ancestral homes, and alienated from their traditions, livelihoods and landscapes. Large-scale quasi-legal and illegal logging and timber trafficking have become the regional norm. Pervasive and deep seated corruption by political and economic elites appears to be the ultimate cause of unrestrained, illegal exploitation of the region’s natural heritage (see e.g., [EIA, 2019](#)).

More recently, rapid expansion of export agriculture continues to perpetuate the process of forest destruction for the benefit of elite national groups and foreign investors. As a consequence, hunger, protein and micronutrient malnutrition among formerly robust forest dwelling people, previously rare because of access to abundant and diverse forest foods, have become more widespread.

Satellite imagery shows other proximate threats include linear infrastructure: roads, railways and power lines, as well as hydro-power development, mining and urbanization. While these are important, in terms of area logged, these are relatively minor compared to agricultural expansion preceded by illegal logging.

In 2011 it was estimated only 5% of Indo-Burma Hotspot habitats remained in “pristine” condition, another 10–25% were considered damaged to varying degrees, but still “ecologically functional” ([CEPF, 2012](#)). Since 2011, the situation has worsened, but full follow-up studies have yet to be undertaken.

By 2014, lowland forests covered only 18 Mha (21%) and upland forests 59 Mha (55%), or 40% of the Mekong region. In brief, some 100 Mha of forest were destroyed in just over 100 years. These historical changes provide background for the discussion on forest cover changes since the beginning of the 21st century to the present.

[Hoare \(2015\)](#) estimated that some 80% of wood products exported from Laos in 2013, came from illegal logging. [Forest Trends \(2018\)](#) documents huge volumes of wood imported by China (and other countries) over 2006–16 from the region, despite export bans being in place. A third source ([Smirnov, 2015](#)) gives detailed evidence of fraudulent documentation and other means used to smuggle some four times the annual national quota of logs and sawnwood from Laos into Vietnam in 2013 and before. A series of reports by the [EIA \(2010-19\)](#) provides additional detail on smuggling from Cambodia and Laos into Vietnam.

In short, there can be little doubt widespread corruption facilitates massive illegal logging and smuggling, and may be the ultimate and greatest current and near-term future threat to the region’s forests. Corruption reduces government revenues from royalties and taxes available for funding basic needs such as health and education services. Without pervasive corruption by government officials—civilian and military—at all levels, large-scale illegal logging and smuggling could not occur.

Key Question

The key question regarding threats to Mekong forest ecosystems and biodiversity is: *What has caused the escalation of forest degradation and destruction during the last 20 years?*

Assessing Forest Destruction in the Mekong Region

The initial global dataset ([Hansen et al., 2013](#)) used by GFW (and others) covered the period 2001–12, it now extends to 2018. It was one of the first satellite-based analyses to systematically document global forest destruction (deforestation), based on 30-m resolution Landsat imagery. This dataset includes all forest canopy cover classes (from < 25% to > 75%). This and two sources noted below have estimated classification accuracies of about 95%.

GFW’s work provides a near current, ecologically valid perspective on changes in land and forest cover, at global, national and provincial levels. Their forest definition differs from FAO’s and relies on: ‘biophysical criteria (height, canopy cover and extent of trees) ... monitors all forms of tree cover including natural forests and tree plantations.’ ([GFW, 2016](#)), it defines a ‘forest’ as an area with > 30% canopy cover and at least 5 m in height. It includes all types of forest cover, official and unofficial, based on pixel-by-pixel and grouped classification and analysis of Landsat imagery; it is preferred by environmental scientists and ecologists.

The following analyses are based on GFW’s data and analysis, supplemented by deeper analysis of the main causes (drivers) of forest loss by [Curtis et al. \(2018\)](#) and [Zeng et al., 2018a](#).

The Mekong region lost over 12 Mha (11.3%) of forest with over 30% canopy cover between 2000 and 2017, roughly equal to two-thirds of the total land area of Cambodia. The area of loss was greatest in Myanmar and least in Thailand; Cambodia lost a quarter of its remaining forests during this period.

Almost all level or undulating land along the Mekong mainstream and tributary valleys and on plateaus has long been cleared for agriculture. Old-growth forests survive only in remote and upland areas. The region's push for hydropower has flooded many river valleys allowing access to illegal loggers and poachers.

Forest destruction has expanded into formerly intact remote upland forests during the last decades, accelerated by the region's integration into global markets for land-based export commodities which now cause significantly more forest destruction than industrial logging. New mines, hydropower dams and reservoirs, and increasing forest fragmentation by new and upgraded roads worsen the situation.

As in over 100 other countries, forest clearance for commodity production is generally preceded by (illegal) logging operations, though it may not be classified as such; Lebloisy et al. (2016) show agricultural commodity expansion for export is closely related to deforestation. In all five Mekong countries government policies plus donor support, have been promoting logging as an approach to rural and regional economic development, despite mounting evidence that human health and biodiversity are being adversely affected.

Regional Forest Destruction

Fig. 4 illustrates the area of forest canopy cover classes for the five countries in 2000, the baseline for analyses of changes over 2001–17. Of total regional forest area (107 Mha), one quarter was 'medium' forest (canopy cover 50–75%) and two-thirds of the area 'dense' forest (canopy cover > 75%)—Laos had the highest and Thailand the lowest percentage of dense forest.

GFW's analysis (Fig. 2) has recently been complemented by analyses of 'dominant drivers' of forest loss conducted by Curtis et al. (2018).

Intense forest destruction, while common throughout the region, has clearly been concentrated in specific, usually upland, areas in each country, a pattern confirmed by Zeng et al. (2018b). The largest portion of forest losses (77%, > 6 Mha over 2000–14) were in the uplands (> 300 m asl), compared to lowland losses of ~4 Mha—from a total over 9 Mha. The greatest losses were in:

- Cambodia—across a broad central swathe and close to the Thai and Vietnamese borders;
- Laos—all across the north and close to the Chinese and Thai borders;
- Myanmar—northeast uplands close to China and the southern region;
- Thailand—northwest uplands and most intensively in the southern peninsular; and
- Vietnam—northeast, close to China and throughout the central uplands from north to south.

Destruction of forest with over 30% canopy cover amounted to 12.1 Mha over 2000–17. Proportionately, losses in Cambodia were the greatest—almost a quarter of its 2000 forest area—Laos and Vietnam each lost about one seventh of their forests. In terms of area, Myanmar lost the greatest amount, a quarter of total regional losses (Table 1). High quality old growth forest (> 75% canopy cover) comprised the great majority of regional losses.

Fig. 4 Mekong region—area of forest ecosystems with over 30% canopy cover destroyed 2003–17. Source: Based on data from Global Forest Watch. 'Tree cover loss in Cambodia, Laos, Myanmar, Thailand, and Vietnam'. Accessed on 09Nov18 from www.globalforestwatch.org.

Table 1 Mekong region—forest cover losses 2000–17.

Country	2000	2017	Loss 2000–17	
	Tree cover (> 30%) Mha	Mha	Mha	%
Cambodia	8.81	6.75	2.06	23.4
Laos	19.13	16.42	2.71	14.2
Myanmar	42.86	39.76	3.10	7.2
Thailand	19.96	18.17	1.79	9.0
Vietnam	16.55	14.14	2.42	14.6
Mekong	107.32	95.24	12.08	11.3

Notes: Calculations based on data from Global Forest Watch. 'Tree cover loss in Cambodia, Laos, Myanmar, Thailand, and Vietnam'. Accessed 09 Nov 18 from www.globallforestwatch.org.

By 2008 the Mekong region was losing almost 0.5 Mha of forests annually. After 2014 this jumped to 1.0 Mha year⁻¹ and in 2017 to 1.3 Mha year⁻¹. Since 2001, and in each subsequent 5-year period, the area of forest destroyed and rate of loss have doubled every 5 years—it is now equal to total regional forest destruction during the first 5 years of the 21st century—Figs. 4 and 5.

Stop Press: In 2018 an additional 1.1 Mha of forest was destroyed, nearly two-thirds being medium forest and one third dense (possibly primary) forest.

Country-Level Forest Destruction

Prior to 2003 the area of annual forest destruction in each country was less than 50,000 ha year⁻¹, and total regional losses about 0.2 Mha year⁻¹ (GFW data). By 2004 it had risen to 60–100,000 ha year⁻¹ and total regional losses to over 400,000 ha year⁻¹. In only 5 years (2013–17) Myanmar lost over 3% of its remaining forests, Laos and Vietnam only slightly less.

In 2003 the rate of loss (Fig. 5) in all five countries was about the same, over 2012–17 losses in Cambodia increased rapidly to about 30% of its remaining forest area, with Laos and Vietnam following a slightly slower trajectory.

Roughly half the Mekong region is above 300 m in altitude. In 2000, in four countries 58%–94% of forests (64 Mha) were in the uplands; Cambodia was the exception with only 20%. By 2014 upland forest area had declined to 59 Mha. Upland forest losses in these four countries ranged from 61% in Thailand to 94% in Laos (Zeng et al., 2018a).

Fig. 5 Mekong region—rate of forest ecosystems destroyed—2001–17. Based on data from Global Forest Watch. 'Tree cover loss in Cambodia, Laos, Myanmar, Thailand, and Vietnam.' Accessed on 09Nov18 from www.globallforestwatch.org.

Analyses of satellite data identified agricultural expansion, preceded by illegal logging, in regional uplands as the cause of about 90% of forest destruction (ibid). This included primary and protected forests, recovering secondary forests, and former swidden lands.

Primary Tropical Forest Ecosystems Destroyed

Percentage canopy cover was used as a proxy for forest quality, species richness and resilience. Forest ecosystems with over 50% cover are considered to be old growth forests; those with over 75% cover are often intact primary forests.

Analysis for 2000 and 2017 compared the relative quality of forests destroyed (total ~12 Mha) based on density of canopy cover. At a regional level, losses were greatest in dense, high quality forests which suffered two-thirds or more of total losses, and in medium density forests which lost about one-quarter of their total area. This broad, long-term pattern of accelerating destruction of high quality forests is illustrated in Fig. 6.

Mangrove Ecosystem Destruction

Coastal mangrove ecosystems are vital for sustaining aquatic production and a critical element in subsistence food supply. Additionally, mangrove coastal barrier forests have become increasingly important as sea levels rise and the frequency and intensity of extreme weather events increase due to global warming.

All Mekong countries except Laos have mangrove forests, these covered some 1 Mha in 2000. By 2014 about 100,000 ha had been lost to different forms of land use change. Since 2014 the trend of habitat loss has likely continued and the rate of loss increased (Richards and Friess, 2016).

In Myanmar mangroves ecosystems were destroyed by conversion to rice fields and aquaculture, to a lesser though significant extent, by wood, pole and fuel harvesting and charcoal production (42,000 ha). In Cambodia aquaculture (11,000 ha) and oil palm in Thailand (43,000 ha) were the main causes, Vietnam lost the least area (3000 ha). Urbanization was not a significant factor (ibid).

Erosion of the Mekong Delta in Vietnam, due to upstream dam construction is leading to changes in Mekong hydrology causing reductions in sediment transport and deposition and nutrient flows, endangering mangroves and other forests in the delta (MRC, 2017) and is exacerbated by rising sea levels.

Loss of Flooded Forests—Tonle Sap, Siphandon and Mekong River

The Great Lake Tonle Sap in Cambodia covering some 3500 km² is long and shallow in the dry season. At the peak of the monsoon it expands to around 14,500 km² and its volume increases by ~40 times to 1.5 km³. Probably the most productive freshwater fishery in the world, some 500,000 tons of fish are harvested during and after the monsoons.

Fig. 6 Mekong region—quality of forest ecosystems destroyed—2001–17. Based on data from Global Forest Watch. 'Tree cover loss in Cambodia, Laos, Myanmar, Thailand, and Vietnam'. Accessed on 09Nov18 from www.globalforestwatch.org. Note: Forest destruction has been greatest in the highest quality regional forests—equating with the most significant cause of rapidly intensifying habitat and biodiversity losses.

The permanent lake is surrounded by ‘flooded forests’ of freshwater mangroves and water-tolerant trees and shrubs. These are breeding grounds and nurseries for hundreds of species of fish and habitats for a broad range of birds and other wildlife. Nutrients washed into the lake and detritus from the forest make the water nutrient-rich. Historically this flooded forest covered some 7000 km², but due to clearing for agriculture and logging it is badly degraded and only about half of its former size.

Further upstream, seasonally flooded forests are situated just above the 20 m high Mekong falls (Khone Phapheng) on the geological fault at the Lao-Cambodian border, and downstream on the braided section of the Mekong mainstream near Stung Treng in Cambodia. All these are under mounting pressure. No data is available on the extent of degradation or destruction.

Dominant Causes of Forest Destruction

Among the more insidious and corrupt practices is the granting of large agriculture concessions on forested lands. This results in destruction (logging) of forest ecosystems prior to land preparation for plantation crops or trees. The area logged, commonly illegally, and volume of wood removed for sale prior to clearing is usually not considered in concession contracts or is vastly under-represented.

Forest losses due to the main causal factors increased variably at 12–18% per year. Fig. 7 illustrates forest destruction by the dominant causes between 2001 and 2015, with sharp increases in the rates of loss in 2009–10 and again in 2013–14, and Fig. 8 forest destruction by country and cause at the beginning and end of this period.

The trend of increasing forest destruction appears nearly certain to continue, facilitated, albeit indirectly, by government policies, strategic donors, (e.g. Asian Development Bank [ADB]), and private investors. All encourage agricultural commodity and forestry exports and greater global market integration (ADB, 2014). Rising forest losses parallels continuing implementation of ADB’s so-called Greater Mekong Sub-Region (GMS) strategy and the major infrastructure projects it supports and/or funds.

Figure 9 illustrates regional distribution of forest destruction by three dominant causes for the period 2001–15; color intensity indicates severity. Rotational swidden agriculture is widespread throughout the region and concentrated in highland areas (>300 m). These regenerate naturally as secondary forest after being left fallow for at least 5–7 years (Fox 2000). Forest losses to urbanisation are minor (<1%) and barely visible (regional total ~24,000 ha over 2001–15).

Infrastructure Development as an Ecosystem Destroyer

Authors stress different but significant threats to regional forests (e.g. Kissinger et al., 2012a,b, Costenbader et al., 2015). Those commonly cited are rarely quantified or prioritized. The key question is the relative scale of these threats, singly or in combination. One threat infrequently mentioned is habitat fragmentation by infrastructure. Some contend it is as great a threat as forest destruction (Fraser, A. pers. comm.; Saravia et al., 2018). It is anticipated increasing destruction and fragmentation of forest habitats and connectivity will result from planned infrastructure projects, leading to cascading and widening negative effects on ecosystems and biodiversity (Balmford et al., 2015).

Fig. 7 Mekong region—dominant causes of forest destruction 2001–15. Based on data from Global Forest Watch. ‘Tree cover loss in Cambodia, Laos, Myanmar, Thailand, and Vietnam’. Accessed 09Nov18 from www.globalforestwatch.org.

Fig. 8 Mekong region—forest destruction by dominant causes—2001 and 2015. Based on data from Global Forest Watch. ‘Tree cover loss in Cambodia, Laos, Myanmar, Thailand, and Vietnam’. Accessed on 09Nov18 from www.globalforestwatch.org.

While, in theory at least, logged primary forests can recover as secondary forests, along with remnants of biodiversity, major physical barriers like roads, railways and energy corridors permanently fragment landscapes, endangering, inhibiting or preventing wildlife movement essential for accessing (seasonal) food sources, water and salt, and species dispersal or migration for reproduction. Moreover, roads and reservoirs provide easy access deep into forest landscapes for hunters and poachers, well known as major threats to wildlife in remaining old-growth forest ecosystems (e.g. Hill et al., 2011; Kleinschroth et al., 2019). ‘When a new road penetrates intact forest, it can facilitate illegal deforestation, poaching, fires and land investors ...’ (Laurance, 2018).

ADB (2012) is an important funder of infrastructure development via its GMS development strategy. For two decades improving transport networks to facilitate domestic and international trade has been high on the agenda of ADB and other donors, and lies at the core of ADB’s GMS strategy of improved ‘connectivity’ (Stone and Strutt, 2009). The negative effects of new roads facilitating illegal logging, poaching and trafficking was recognized over a decade ago (ADB, 2008). Negative impacts on forest integrity and connectivity have significantly increased since then (recall the Thai road network depicted in Fig. 1).

Central to China’s new Belt and Road Initiative (BRI) in the region is a north-south high speed railway running through Laos and Thailand, and possibly onward through Malaysia to Singapore, cutting a swath through some of the remaining primary forests in Laos and displacing thousands of farming families. Rail traffic is a major danger to both humans as well as domestic animals, elephants and other wildlife. Broadly, BRI infrastructure investments present a series of serious environmental assessment and management problems, including directly destroying, further fragmenting and increasing access for logging in the remaining forest landscapes (Ascensão et al., 2018). These risks have not yet been properly assessed.

Rapid Rise of a New Threat

The rapid rise and increasing scale of regional forest destruction suggests a new threat emerged in the last decade. Commercial wood from large areas of forest, nominally being cleared for agriculture, is being exported from the Mekong in massive quantities. To explore this, wood export-import data for 2000–17 were analyzed using UN trade data (<https://comtrade.un.org>).

The two largest categories of wood exports from the Mekong region are unprocessed logs and sawnwood, from about 2010 onwards accounting for over half the total. Various bans on export of ‘unprocessed timber’ from the region have been in place since the late 1980s, though enforcement has usually been absent or minimal. Cambodia banned export of ‘timber larger than 25 cm’, i.e. logs and sawnwood in 1996; Laos banned exporting any wood not ‘finished and fully processed’ in 1989, reactivated in 2015; Myanmar banned export of ‘raw logs’ in 2014, Thailand did so in 1989, and Vietnam banned export of logs and ‘sawn timber’ from natural forests in 1992 (WRI/Forest Legality, 2018). In essence these bans cover all wood from natural forests categorized under the UN Commodity Trade Harmonized System as HS4403 (logs) and HS4407 (sawnwood)—making export illegal.

Under WTO rules whether goods are ‘legal’ or ‘illegal’ is not an issue for countries which do not have voluntary bilateral agreements on wood ‘legality’, for example, a Voluntary Partnership Agreement banning log and sawnwood exports or imports. However, wood imports (legal and illegal) are recorded by customs officials, as governments need this data to calculate import duties and

Fig. 9 Mekong region—forest destruction by dominant cause—2000–15. Notes: Each colored square 10 km × 10 km = 100 km². Dominant deforestation drivers: red = commodity production, green = industrial logging, yellow = shifting agriculture (swidden). Based on Curtis, P.G., Slay, C.M., Harris, N.L., Tyukavina, A. and Hansen, M.C. (2018) Classifying drivers of global forest loss. *Science* 361, 1108–1111, 14Sep18, Supplementary Materials: www.sciencemag.org/content/361/6407/1108/suppl/DC1.

taxation. No Mekong country had implemented such an agreement by 2017. As national government forestry and wood trade export statistics for the Mekong are known to be unreliable (Fraser, 2012) UN Commodity Trade statistics were used in preference.

The China Factor

The rapid rise in wood exports (recorded as imports) during 2000–17 (Fig. 10), shows a step-change beginning in about 2010. This was the result of radical increases in imports by Chinese companies of unprocessed wood (logs, sawnwood) and, commencing a few years later, particle and fiber board. By 2017 their combined volume accounted for 80%–90% of all Mekong wood exports—two-thirds of which were logs and sawnwood.

Fig. 10 Mekong region—exports of wood, all categories (2000–17). Notes: Y-axis '000 Tm. The two lower yellow and orange bands are those for logs and sawnwood (HS4403 and HS4407). Note: No adjustment has been made for approximately one-third loss of mass in rough sawing logs to sawnwood, this adjustment would increase the mass of HS4407 exports by this amount. From UN Comtrade Database (www.uncomtrade.un.org).

The apparent decline in exports of logs in 2017—lowest band in Fig. 10—may be due to incomplete data for 2017, but more likely due to logs (HS4403) being misclassified as sawnwood while still in the forest. Hence the significant increase in sawnwood (HS4407) trucked across land borders to evade log export bans (c.f. Smirnov, 2015).

The pattern of forest destruction, volume and value of exports for 2001–17 is illustrated in Fig. 11. There is a high, statistically significant correlation ($r = 0.912$, $f = 0.023$) between the annual area of regional forest destruction, volume and value of annual wood exports during this period. That is, forest destruction provided the wood for (illegal) exports, almost wholly going to China. These are the only two categories of wood in the Mekong region subject to export bans.

Total annual exports of all categories of wood grew from 2 Mt. (USD 2.81 bn) in 2000 to 16.13 Mt. (USD 8.52 bn) in 2017—a radical increase in exports of logs and sawnwood largely drove this change. Fig. 12 shows logs and sawnwood dominated exports over 2010–17, accounting for half or more (45%–73%) of total exports. The great majority of logs and sawnwood were destined for China.

Time series analysis directly links increases in area and rate of forest destruction to (illegal) exports from the region. The strong correlation ($r = \sim 0.70$ to > 0.90) between the volume and value of total timber imports by China, allows discussion to focus on the physical quantities involved.

It is widely accepted significant quantities of wood come from widespread illegal logging in national parks and protected areas, and from clearing for new hydropower reservoirs, mine sites and road upgrading; there are also many credible reports of regional military involvement (e.g. EIA, 2015).

Step-Change in Forest Destruction

Some 80% by volume and 60% by value of total wood exports from the Mekong region during 2000–17 occurred between 2010 and 2017. Rough logs and sawnwood have repeatedly been identified as the main products trafficked from Cambodia, Laos and Myanmar to Vietnam and China (e.g. EIA, 2015, 2017a,b, Forest Trends, 2010, Smirnov, 2015; Schape and Canby, 2018); Smirnov emphasized logs being consistently ($\sim 90\%$) miscategorised as sawnwood, i.e. 'processed wood,' to evade export bans.

Logs and sawnwood are eminently suited to trafficking, requiring no or minimal processing these can be transported directly across land borders as logs or rough sawn slabs. On-the-ground covert investigation over the last decade revealed the actual scale of illegal logging and trafficking (EIA, 2011, 2012, 2015, 2017a, 2018) even at local border crossings away from main roads.

Fig. 11 Mekong region—forest losses, volume and value of wood exports 2001–17. Notes: Timber export data are based on reported global imports from the Mekong region. From GFW accessed 09Nov18. (www.globalforestwatch.org) and UN Commodity Trade Statistical Database (<https://comtrade.un.org>).

Fig. 12 Mekong region—wood exports by category 2010–17. Notes: Units: Millions of tons (Mt) or 10^6 . Logs and sawnwood (HS4403 & HS4407), particle and fiber board (HS4410 & HS4411), all 17 other timber categories (HS44**). From Calculated from UN Comtrade Database (<https://comtrade.un.org>).

In 2000, China imported about 26% of total exports of logs and sawnwood from the Mekong, in 2017 alone it imported 54% (8.7 Mt) of total wood exports from the region. During 8 years (2010–17) China imported over three-quarters of the region's total wood exports of 69 Mt. (Fig. 13), of this 54 Mt. (69%) were logs and sawnwood.

Wood Exports and Destruction of Primary Forests

For a large Biodiversity Hotspot like Indo-Burma a region-wide perspective is appropriate. From this perspective, it matters not whether forest destruction is legal or illegal—forest ecosystems and biodiversity are destroyed by both.

It is clear the majority of wood exports come from the Mekong's old-growth, often primary forests. The step-changes (2010 and 2014) in forest loss were almost completely the result of significantly increased and continuing destruction of the region's richest forest ecosystems, those with the most complex, complete ecosystems and, arguably, the best wildlife and biodiversity habitats.

Fig. 13 Mekong region—global and Chinese imports, logs and sawnwood (2010–17). Notes: Units Mt. ($\times 10^6$); unprocessed logs and sawnwood. From Calculated from UN Comtrade Statistical Database (<https://comtrade.un.org>).

The combined annual wood exports by the five Mekong countries for 2001–17 illustrates this pattern (Fig. 14). The upper line traces the volume of wood logged and exported from dense (old growth) forest ecosystems.

Over 2001–17 there is a close correlation between volume of wood exports and area of dense old growth forests destroyed ($r = 0.879$, $f = 0.159$). While logging more valuable old growth forests makes financial sense for loggers and importers (who buy high quality wood cheaply), the result is ever more rapid destruction of the region's most ecologically important forests and biodiversity.

Fig. 14 Mekong region—wood exports vs forest losses by canopy class (2001–17). Notes: Exports '000 tons/year by canopy class. Commercial yield based on canopy cover class and average yield per ha (22%); yield per canopy class: <20% $11 \text{ m}^3/\text{ha}^{-1}$, 20–25% $61 \text{ m}^3/\text{ha}^{-1}$, 50–75% $88 \text{ m}^3/\text{ha}^{-1}$, and >75% $137 \text{ m}^3/\text{ha}^{-1}$ (Fraser, Pers. comm.). Calculation based on GFW forest loss data and UN Comtrade export/import data.

Financial Snapshot of Forest Destruction

The financial aspects of logging and wood exports are critical to understanding the process, as massive, unaccounted cash flows facilitate corruption essential for illegal logging and trafficking. Since 2010 the nominal value of wood exports has always been greater than USD 0.5 bn per month and reached USD 1 bn per month in 2014. Fig. 15 is based on the value of imports reported by UN Comtrade.

The regional summary distinguishes between amounts reported for all categories of significantly processed timber and for unprocessed logs and sawnwood. In 2017 the total value of wood exported from the Mekong region was USD 8.52 bn (Fig. 15), well over half this was for logs and sawnwood—China imported almost all (96%) of this wood (cf Fig. 12).

Summary of Findings

Regional governments are complicit partners in allowing forest ecosystems to be ever more rapidly destroyed for private profit. Traditional forest-dwelling communities continue to be victims of this process. The wildlife, much of it endogenous, in these forest habitats has been largely extirpated. There are growing indications the Mekong region's forest ecosystems and unique biodiversity may be nearing a point of collapse (Saravia et al., 2018).

Private financial incentives for illegal logging and timber trafficking are immense. In the absence of bilateral agreements (e.g. VFAs) WTO's international trade rules allow illegally logged and traded wood to be freely imported without penalties. In the absence of such agreements, including effective enforcement, it is regarded as very unlikely that governments in the region will prevent intra-regional and international trafficking. Given this, external action may be the best or only alternative. Chinese companies are clearly the dominant importer of what is plausibly identified as a massive trade in illegal wood, and action by the Chinese government to halt this may offer the best hope for conserving Mekong forests and the global heritage of the Indo-Burma Biodiversity Hotspot.

Since 2000, many of the large areas of intact and primary forests that evolved during the last ~10,000 years (Holocene Era) have been radically disrupted, degraded or destroyed. An unprecedented amount of this has occurred during the past decade. This has been caused by industrial logging, plus agricultural expansion covertly combined with illegal logging, and massive trafficking and illegal exports, mainly to China. With no sign these trends are slowing, threats to critical regional ecosystems of all types and biodiversity in the Mekong appear set to increase in coming decades (Corlett, 2013).

Concluding Remarks—Politics of Conservation

A recent assessment of conservation priorities and capabilities in the Mekong region was prepared by CEPF (2017). It builds on earlier assessments in 2008 and updated in 2011. It notes a major decline in donor funding for biodiversity conservation amid increasing threats; significant funding being switched to addressing threats from global warming.

It identified >400 Key Biodiversity Areas (KBA) and 66 'conservation corridors', from which a region-wide priority investment list was prepared. Most terrestrial KBA are located in or are forests, of which in 2015 only a minor proportion (13%) were 'protected' by national laws and regulations (Weller et al., 2017).

The assessment explicitly recognizes the vital role civil society has to play in conserving biodiversity, as without being able to freely (and safely) contribute it is very unlikely conservation goals can be achieved. The report identified three criteria needed to achieve and maintain national capabilities for ecosystem conservation to achieve a 'transition' away from relying on investments and technical support from donors. These were:

Fig. 15 Mekong region—value of wood exports 2010–17. Calculations based on UN Commodity Trade Statistics Database.

- *Political stability*—the absence of war or civil strife—considered likely for all five countries;
- *Economic stability* (and resilience)—considered likely, except for Myanmar and Laos; and
- *Open political environment*, considered ‘most open’ in Vietnam and Thailand, ‘intermediate’ in Cambodia and Myanmar, but ‘unfavorable’ in Laos. (However, the situation for civil society in Cambodia, Myanmar and Thailand has deteriorated since the CEPF report was prepared.)

According to CEPF’s assessment long-term biodiversity conservation and protection success requires that:

- Conservation priorities guide biodiversity conservation investments.
 - Local civil society groups have the capacity, rights, and ability to influence decisions on sustainable societies and economies.
 - Adequate and continual financing for conservation efforts is available.
 - Public policies and private sector operations support conservation.
 - Mechanisms exist to identify and respond to emerging challenges.
- (CEPF, 2017:40).

Given the report’s critical assumptions, especially the need for an ‘open political environment’, the chances of being able to conserve forests ecosystems and their biodiversity in the Indo-Burma Biodiversity Hotspot, Earth’s largest and possibly most threatened, appear to be growing dimmer.

Acknowledgments

Many thanks to my old friend Andrew Mittelman, who’s regional knowledge and critical editing made the text more readable. Percy Allen’s sharp eye identified and corrected errors in language and logic. Not least, many thanks to my wife and partner, Melody Kemp, for editorial support and encouragement.

Heartfelt thanks to Mikaela Weisse and Liz Bourgault of Global Forest Watch/WRI for providing additional access to GFW’s data and analysis on forest cover changes. Special thanks to Philip Curtis who undertook analysis of the dominant drivers of forest destruction with GFW and was generous in further clarifying his results. Thanks also to Zhenzhong Zeng, now of Princeton University, for further analysis of his research findings. Alistair Fraser, friend and colleague, provided insights and data from his archives, based on his extensive forestry work in the region.

Glossary

CO₂e The global warming potential of a molecule of carbon dioxide or other molecules (e.g. methane, nitrous oxide, etc. weighted as if they acted the same as CO₂.

Discount rate Defined in per cent to reflect the time value of money.

Ecosystem services For temperate forests, ecosystem services include gas regulation, climate regulation, water supply, soil formation, nutrient cycling, waste treatment, biological control, habitat/refugia, food production, raw materials, recreation, and cultural services, but are limited to them.

Fair market value (FMV) An estimate of value of real property where both the buyer and seller are comparably knowledgeable of the property, have equal bargaining power and the transaction is voluntary for both parties.

Net present value (NPV) The current value of an investment with future cash flows, appropriately discounted to reflect money today is worth more than money in the future.

Nonraw material ecosystem services (NRMES) All ecosystems services specified for ecosystem services, save for raw materials (fiber, fuel or fodder).

Time value of money Money to be received at a point in the future is worth less than money received today.

Tonne 1000 kg, also called a “metric ton” that can be confused with a “US ton,” “short ton,” “British ton,” “imperial ton,” or “long ton.” As any difference is well within $\pm 2\%$, and as a tonne is a ton of something, do not sweat it.

Abstract

The highest and best uses of US public and private forestlands (e.g. carbon sequestration and storage, biological diversity, ecosystem function, watershed integrity, and aesthetic enjoyment) are severely diminished by the most common uses of forests: logging for the production of fiber for construction and paper products. This irreconcilable conflict between the value of private forestlands for private profit and their societal value by the provision of nonraw material ecosystem services can be ameliorated by large-scale fiber switching from trees (multidecadal, centennial and even millennial fibers) to fiber grown on farms (annual, biennial and at most decadal fibers). Such a transition is technically feasible and can be economically feasible if markets demand it and/or government requires it. Many species can be farmed for fiber that can make comparable or superior construction and paper products. No conflict with food production is projected. As private forestlands are retired from fiber production they can be dedicated to their highest and best uses by conversion to public ownership by sale from willing sellers. Workers that lose jobs in the transition would be compensated, as would local governments for lost tax revenues. Funding for a migration of most US fiber production from forests to farms can be met by either a modest increase motor fuel taxes or a very modest tax on carbon emissions.

Introduction

The inherent and irreconcilable conflict between the logging of forests for fiber or fuel and conserving and restoring forests for ecosystem services—including, but not limited to, carbon storage and sequestration, biological diversity, ecosystem function, watershed integrity, and aesthetic enjoyment—has caused many a forest aficionado to cry out for alternative fibers with which to make construction and paper products that today are mostly manufactured from tree flesh (commonly known as wood).

The good news is that it is technically feasible to migrate most US fiber production from forests to farms. There are tree-free fiber alternatives—both fibers from agricultural waste products from existing crops and from intentionally grown fiber—that can meet most US demand for fiber. This demand can be met from annual, biennial, and—at the most—decadal fiber crops, all grown on farmlands. The multidecadal, centennial, and millennial fibers (commonly known as trees) that grow on forestlands can be dedicated to their highest and best uses: the provision of nonraw material ecosystem services (NRMES).

The bad news is that presently, the widespread replacement of forest fiber with farm fiber is not economically feasible. However, a combination of market demand, government purchasing policies, government regulation, and reallocation of government subsidies can result in a massive changeover of fiber feedstocks. The results would be more sustainably managed forestlands and more sustainable and profitable farmlands.

The great news is that industries change in response to market demand and/or government policy. Political and market demands—for forest conservation, cleaner and more water, sustainable products, and a climate somewhat near what we have known and loved—can converge to make the transition of fiber feedstock from forests to farms a reality.

This article relies on “Migrating Most US Fiber Production from Forests to Farms: A Model,” an Excel workbook (here after “fiber migration model” [FMM]) developed by the author (Kerr, 2018).

Irreconcilable Conflict in Forest Management: Fiber or Nonraw Material Ecosystem Services

US professional forestry has two major camps: production forestry and ecological forestry (Table 1). Production forestry (Bettinger et al., 2016) is dominant, but as public and private forestland owner preferences continue to evolve, ecological forestry (Franklin et al., 2018) is gaining landowner and social acceptance.

Table 1 Fundamental contrasts between ecological forestry and production forestry

<i>Ecological forestry</i>	<i>Production forestry</i>
Maintains an array of ecosystem structures, function (processes), and biota at larger spatial scales	Maintains a limited set of ecosystem structures, function and biota consistent with economic goals
Emphasizes ecosystem diversity and resilience to reduce risks from major ecosystem disruptions	Emphasizes fast-growing species on short rotations to reduce financial risks
Tends to increase management and social options	Tends to reduce management and social options
Values complexity and heterogeneity	Values simplicity and homogeneity
Accommodates landowner and social goals by adjusting the ecological model	Accommodates landowner and social goals by adjusting the economic/agronomic model

Reprinted by permission of Waveland Press, Inc. from Franklin JF, Johnson KN, Johnson DL (2018) Ecological forest management. Long Grove, IL: Waveland Press, Inc., ©2018 All rights reserved.

For the provision of NRMES, ecological forestry is far superior to production forestry—but still inadequate compared to the full conservation and restoration of forestland. (DellaSala et al., 2013) For the provision of fiber, production forestry is superior to ecological forestry—but is unsustainable.

There is an irreconcilable conflict between conservation and fiber production on forestlands. Both production forestry and ecological forestry assume that since fiber for US paper and construction products have historically come from wood that such fiber can only come from wood. However, this conflict can be mostly resolved by increased use of farm fibers.

Private Value Versus Societal Value of US Forestlands

There is a huge disparity between the worth of US private forestland to a private landowner and what that same land is worth to society. Private value accrues from the sale of raw materials, while societal value comes from the enjoyment of NRMES. Private profit has a social cost.

Fair Market Value to Private Landowners of Private Forestlands

The fair market value (FMV) of an average acre of US private forestland is \$1823 (\$4505/ha) (Mendell, 2017). Though the average value, the range of land values is wide and dependent upon site productivity, species composition, distance to markets and other factors. Assuming a 5.5% rate of return (or discount rate), the average income on the average acre is ~\$80/acre/year (\$198/ha/year).

Fair market value (FMV) is an estimate of value of real property where both the buyer and seller are comparably knowledgeable of the property, have equal bargaining power and the transaction is voluntary for both parties (Macaraeg, 2018).

FMV is mostly based on the ability of the forestland to produce fiber and/or land appreciation. Private forestlands with development potential have higher value than those valued for just timber. For the private forestland owner to fully realize profit, forestland must be intensively managed for fiber production, which usually involves clearcutting and short-rotation timber harvesting. Alternatively, if the market exists, the forestland can be sold for development for at a higher value than for timber production.

Net Present Value to Society of Private Forestlands

“Ecosystems provide a range of services that are of fundamental importance to human well-being, health, livelihoods, and survival.” (Costanza et al., 2014).

For temperate forests, ecosystem services include a variety of values of benefit not only to the private landowner, but to society as a whole (Costanza et al., 1997). The value of NRMES to society from an average acre of temperate forest is \$1364 each year (\$3371/ha/year) (Table 2). The value of raw material (fiber, fuel, or fodder) ecosystem services is \$84 per acre per year (\$206/ha/year), or 6% of total temperate forest ecosystem services annual value (Costanza et al., 2014).

Net present value (NPV) is a way to quantitatively value an investment, in this case private timberland. NPV is current value of an investment factoring anticipated future cash flows using an appropriate discount rate to reflect the time value of money—money today is worth more than money in the future (Gallo, 2014). The higher the discount rate, the less the value of the investment. In determining the societal NPV of NRMES, the FMM considered three discount rates (Table 3):

- 5.5%, the average rate used by of over 80% of industrial timberland owners (Lyster et al., 2017);
- 2.6%, the present rate of the U.S. government (Office of Management and Budget, 2017); and
- 0%, the rate at which future generations are valued the same as the present generation.

Table 2 Quantified ecosystem services for temperate forests (\$2018)

<i>Ecosystem service</i>	<i>\$/Acre/year</i>	<i>\$/Hectare/year</i>
Climate regulation	\$70	\$173

2.6%	US Government	$\$28 \times 10^3$	$\$69 \times 10^3$	$\$162 \times 10^3$	$\$400 \times 10^3$	$\$16 \times 10^6$	$\$40 \times 10^6$
0%	Intergenerational equity	$\$37 \times 10^3$	$\$91 \times 10^3$	$\$828 \times 10^3$	$\$2.0 \times 10^6$	$\$312 \times 10^{15}$	$\$771 \times 10^{15}$

Kerr A (2018) Migrating most US fiber production from forests to farms: A model. Ashland, OR: The Larch Company.

It is usual for an NPV analysis for private forestland to have a discount rate higher than that of the government. It is unusual to use 0%. An NPV analysis also requires defining an investment horizon. Private timberland investments are often 5 to 25 years with an average of 10 years (Bullard et al., 2002). It is also highly unusual to use an NPV time horizon of greater than 20 years. Choosing a longer investment horizon results in less intergenerational inequity. To reflect the premise that this generation should make decisions with future generations in mind, the FMM considered 20, 100, and 1000 years.

Even using the highest discount rate (5.5%) with the shortest analysis period associated with NPV to private landowners (20 years), the societal NPV of NRMES provided on an average parcel of US private timberland is \$20,000 per acre (\$49,000 per hectare) If one considers longer time horizons (after all, NRMES are not a depreciating societal asset) and assumes that members of a society in the future are just as valuable as members today, then the NPVs attain astronomical values (Table 3).

Contrasting Private Fair Market Value and Societal Net Present Value of Private Forestlands

In theory, and with a rational market, NPV equals FMV. The only way that a US private timberland owner can monetize their investment is to log (or develop), at the expense of NRMES values to society. If society fully compensated private landowners for ecosystem services received from US private forestlands, an average acre of private forestland would have an FMV of, at a minimum, ~\$20,000 (\$49,000/ha)—the private FMV would be equal to the societal NPV. But society does not pay private landowners for the NRMES it receives from private forestlands. The average FMV is \$1823 per average acre (\$4505/ha). The societal NPV for that same average acre is at least \$20,000 (\$49,000/ha), a mismatch of over 11 times. When rational outcomes for private landowners do not lead to a rational outcome for society, economists call it a market failure (Investopedia, 2018).

The Most Common Use of US Forestland Is Fiber Production

The US has 766 million acres (310 million hectares) of forestland, of which 521 million acres (211 million hectares (68%) is timberland (Table 4). About 10%, 74 million acres (30 million hectares), is reserved for conservation and other purposes. Some of the reserved lands are logged, albeit to a lesser degree than timberland. Some logging also occurs on “other” forestlands, including woodlands and scrub forests. The most intense logging is on industrial timberlands and nonindustrial owners who manage their forestlands with an industrial mindset. The US also has 53 million acres (22 million hectares) of woodlands (< 10% covered with

trees). Most timber volume comes from private forestlands, which account for 56% of all forestland. Forty two percent of all forestland is owned by individuals and families who often own their forestlands for the enjoyment of their aesthetic value and wildlife activity. Almost half of these lands are owned by people over 65 (Oswalt and Smith, 2014).

Current US Forest Fiber Use

With 5% of the world's population and 7% of the world's land area, the United States has 8% and 10% of the world's forest land and timber inventory respectively, and uses 28% of the world's timber for industrial products (Oswalt and Smith, 2014).

In 2017, the US produced 335 million tonnes of finished wood products, of which 61 million tonnes were exported and an additional 39 million tonnes were imported. Production plus imports, totaling 375 million tonnes, equals US consumption (UN Food and Agriculture Organization, 2018). Sawnwood—lumber and other products made of solid wood—were ~15% of the total forest fiber produced and imported (Table 5).

Table 5 US major forest fiber product groups finished products (2017).

Highest and Best Use of US Forests Is Nonraw Material Ecosystem Services

NRMES are degraded by logging (Norse, 1990). The more forestland area that is logged and/or the more intensely the logging on each parcel, the less NRMES are available from that forestland parcel.

All ecosystem services provided by forestland are eliminated by development, which results in complete deforestation. Development is causing not only the direct loss of forestland cover, but also of interior forest, which intactness is more beneficial to wildlife and other forest values. From 2001 to 2006, the US had a net loss of forests of 1.2%, while the loss of interior (intact) forest was 4.3%. (Oswalt and Smith, 2014) Such fragmentation leads to losses of species, habitat, gene pools, biological diversity, biomass, and natural processes, and altered nutrient cycles (Haddad et al., 2015).

While the most common use of public and private forests in the United States is logging for fiber, such is not the highest and best use—and especially so if there are alternative sources of fiber.

Securing the Value of Ecosystem Services on US Forestlands for This and Future Generations

The market for US forestland incentivizes logging or developing forests for profit. Since society cannot rely on the market to continue to provide NRMES over time, other methods must be sought to achieve forest conservation.

This could mean better regulation of logging on forestlands, but the level of regulation adequate to secure the continuation—if not expansion—of nonraw material forest ecosystem services would be politically unacceptable. Governments could pay a forestland owner not to log or develop by acquiring the timber and development rights. As the cost of the rights to log and develop a parcel is often a very high fraction (especially in the case of development) of the entire market value of the private forestland and there is also an ongoing monitoring and enforcement cost which can be expensive (Schuster and Arcese, 2015), it would often be more cost-effective to convert the private timberland to public forestland by acquiring the land outright so it could be fully managed for NRMES values.

Alternative Agricultural Fibers

A 1994 comprehensive literature review found 53 alternative fibers had been considered for the production of building materials. These included plants intentionally grown for fiber, but mostly materials left over after processing a plant for its intended purpose (sugar, nuts, grain, fruit, etc.) (Youngquist et al., 1994, 1996). Much research on and utilization of agricultural waste fibers occurs outside the United States in nations that have abundant agricultural waste fiber and little to no forest fiber availability (Dungani et al., 2016).

Technically, there are several annual, biennial or, at most, decadal farm fibers that could replace (Table 6) the multidecadal, centennial, and even sometimes still millennial forest fibers. There are three categories of farmland fiber that could displace forest fiber consumption at meaningful scales:

- (1) waste fibers (fibrous waste products left over after harvest or primary processing);
- (2) intentional fibers (grown for the purpose of harvesting fiber); and
- (3) trees grown on farmland (not on forestland, and with extremely short rotations).

Technically Feasible

From a technical standpoint, fiber is generally fungible. Paper and construction products can be made out of almost any fiber (Brand, 1911; Youngquist et al., 1993; Miller, 1975; Rowell et al., 1997; Bowyer et al., 2004; Ashori, 2006; Enayati et al., 2009; Langholtz et al., 2016; Favero et al., 2017; Fahmy et al., 2017; Heller, 2017; Economist, 2018). Farm fiber can also be used to produce paper board, hardboard particle board and other construction products (Youngquist et al., 1993; Li et al., 2014; Sam-Brew and Smith, 2015; Fahmy et al., 2017; Lühr et al., 2018; Mirski et al., 2017; Sam-Brew and Smith, 2017; Mirski et al., 2018).

Ashori (2006), Bowyer et al. (2004), Enayati et al. (2009), Fahmy et al. (2017), Heller (2017), Langholtz et al. (2016), Miller (1975), Rowell et al. (1997), Thomas and Liu (2013), and Youngquist et al. (1993).

Availability

There can be nearly 700 million tonnes of US farm fiber that is available to replace forest fiber in a sustainable manner (**Table 7**). Nearly 200 million tonnes is byproducts from existing agricultural crops, either as crop residue on the field or waste from primary processing (e.g. hulls, peels, etc.) (**Fig. 1**). Utilization scenarios modeled by the US Department of Energy (USDOE), do not consider all crop residues as available—enough is reserved to maintain soil organic carbon and soil nutrient recycling (Langholtz et al., 2016). These residues and wastes are available today but are usually burned off, contributing to climate change and air pollution.

Nearly 500 million tonnes annually of intentional fibers is what the USDOE analysis says could be sustainably grown on farmland without competing with demand for food, livestock feed, fiber, and timber (including export products) (Langholtz et al., 2016). USDOE's interest in biomass energy dictated its choice of which herbaceous and woody crops it modeled. Biomass is mostly fiber, so the acreage is available to grow intentional farm fiber crops destined for paper and construction products.

Substitution Potential

Wood has been the nation's go-to source for construction and paper products because of its abundance and physical qualities. However, there are other fibers with comparable or superior physical qualities than could be obtained and utilized in abundance, so that forestlands could be conserved and restored without a diminution in available fiber for products.

To reverse the loss of both the quantity and quality of forests, US farm fiber must replace a very significant amount of US forest fiber. The more fiber production is migrated from forests to farms, the more NRMES than be obtained from forestlands.

While 100% replacement would be perfect from a forest perspective, absolutes are rarely good public policy or economically attainable. The marginal additional costs of attaining the last increments often requires extremely high costs.

US forest fiber products can be grouped into three major categories:

- pulp and paper (54%);
- wood-based engineered composites (smaller pieces of wood that is not reduced to pulp before use) (32%); and
- sawnwood (solid wood products) (15%).

Table 7 Technically available agricultural substitute fibers (million tonnes) per year.

Existing byproducts	188
• Agricultural residues	171
• Agricultural wastes (from primary processing, not animal manure)	18
Intentional agricultural crops grown on farmland	496
• Herbaceous crops (switchgrass, Miscanthus, energy cane and biomass sorghum)	445
• Woody crops (willow, eucalyptus, poplar, pine)	51
Total	684

Langholtz MH, Stokes BJ and Eaton LM (leads) (2016) *2016 Billion-ton report: advancing domestic resources for a thriving bioeconomy, Volume 1: Economic availability of feedstocks*. Oak Ridge, TN: US Department of Energy Oak Ridge National Laboratory.

Fig. 1 Bagasse is the dry pulpy residue left after the extraction of the juice from sugar cane. Courtesy of TreeZero.

Technologically, the substitution of farm fiber for forest fiber is substitutable to varying degrees:

- Highly substitutable (95%): Pulp and paper (Figs. 2 and 3).
- Very substitutable (75%): Wood-based engineered composites (Figs. 4 and 5).
- Substitutable (50%): Sawnwood (Fig. 6).

The substitution estimate for sawnwood is very conservative as processing and engineering could result in a higher rate of substitution.

Engineering and Innovation

Though fiber is generally fungible, the farm-fiber feedstocks will be different enough from forest-fiber feedstocks to require additional, or at least different, engineering and innovation to profitably manufacture paper and construction products. The largest volume of farm fiber could come from waste fiber from existing crops. The remainder could come from crops intentionally grown for fiber, such as hemp (Fig. 7).

A particular challenge with hemp is the efficient separation (decortication) high- and low- value fibers found respectively on the outside and inside of the stalk (Cherney and Small, 2016; Tahir et al., 2011). Another challenge is the storage and timing of shipping agricultural fibers to processing facilities. Wood, because of its high lignin content, can be stored exposed to the weather and can be harvested much, if not all, of the year. Farm fibers cannot be stored outdoors, are often far bulkier than farm fiber, and the harvest (Fig. 8) is mostly a short window in the fall (Fike, 2016).

Irreplaceable Wood Products

Most, but certainly not all, products could be made from farm fiber rather than forest fiber. For some products, because of technical or quality reasons, farm fiber is just not substitutable—though most of these products have their nonwood substitutes. Wine casks, whiskey barrels, musical instruments, firewood, popsicle sticks and baseball bats made from wood are often preferred by the market for their quality and/or tradition. Budweiser® beers are aged with beechwood chips (Goldman, 2016) and need not change. In certain cases, the highest and best use of forest fiber is wood products.

Economics of Nonwood Plant Fiber and Changing Consumer Demand

Today, in almost all cases, forest fibers out-compete farm fibers in terms of delivered price to processing facilities. For example, hemp pulp in Europe costs five times that of wood pulp (Cherney and Small, 2016). Not that one needs to use 100% hemp

Fig. 2 Made of bagasse, this tree-free office paper is indistinguishable from that made from wood. Courtesy of TreeZero.

Fig. 3 A tree-free paper towel made of bamboo and bagasse. Courtesy of Who Gives a Crap.

Fig. 6 3-ply bamboo. Courtesy of Kirie.

pulp to substitute for 100% wood pulp, but rather one could use a blend of the more-expensive hemp fiber with the less-expensive agricultural waste fiber. Still, the price differential is large.

The current infrastructure of the manufacture of building products is based on forest fiber and facilities were built near forests and not farms. Agricultural waste fiber is bulky and therefore expensive to transport long distances.

However, markets respond to consumer demand as well government policies, be they the stick of regulation or the carrot of subsidy. The projected 20-year migration period allows time for an orderly and efficient transition.

Successful firms respond to market demand. As consumers demand, suppliers will meet that demand. However, there is very little demand for nonwood paper and construction products primarily because there is very little supply of nonwood paper and construction products. Determined consumers can identify such products, but they are hard to find and are of limited variety.

Intentional Fiber

There are several fibers that could serve as intentionally grown farm fibers *Arundo donax* (known as giant cane, giant reed or other names), bamboo, hemp, jute, kenaf, and rice (Table 6). While the market will ultimately decide, the most favorable intentional fiber(s), hemp was chosen for the fiber migration model because of superior technical qualities. However, because of the effective illegality of cultivating hemp in the US since 1937, hemp is a current disadvantage. As the Congressional Research Service notes: "Most researchers acknowledge the potential profitability of industrial hemp, but also the potential obstacles to its development. Current

Fig. 7 A field of hemp. Wikipedia Commons Creative Commons Attribution-Share Alike 3.0 Unported.

Fig. 8 The harvest of hemp in France. Courtesy of Ralf Pecenka/Leibniz Institute for Agricultural Engineering and Bioeconomy (ATB). Permission granted.

challenges facing the industry include the need to reestablish agricultural supply chains, breed varieties with modern attributes, upgrade harvesting equipment, modernize processing and manufacturing, and identify new market opportunities" (Johnson, 2018).

Hemp

The term "hemp" is used to describe certain varieties of the species *Cannabis sativa* L.). Other certain varieties of the same species are called "marijuana." "Industrial hemp" is often used to distinguish hemp from marijuana. Marijuana is bred to have a high amount of Δ^9 -tetrahydrocannabinol (THC), the intoxicating cannabinoid in *C. sativa*. Hemp strains have insignificant amounts of THC and far high amounts of another cannabinoid, cannabidiol (CBD), which though also psychoactive, is not intoxicating (Cherney and Small, 2016).

In 2018, hemp was fully legalized by Congress. Hemp is no longer legally considered to be marijuana. While previous US law nominally allowed for the hemp cultivation, as a practical matter it did not happen because the Drug Enforcement Administration treated hemp and marijuana as one in the same (Kerr and Moran, 2016).

Hemp is an agricultural commodity cultivated for a wide variety of products including foods, beverages, cosmetics, personal care products, nutritional supplements, fabrics, textiles, yarns, spun fibers, paper, construction materials, insulation materials, auto parts, animal bedding, oil absorbents and other manufactured goods. Hemp is cultivated to maximize seed or fiber or both (Johnson, 2018).

Hemp fiber comes in two kinds (Fig. 9). The outer ring of the plant is composed of long phloem (“bast” or “bark”) fibers. The inner core of the plant is composed of short xylem (“wood”) fibers. With the remnants of stem pith, the nonbast fibers are collectively known as “hurd.” The long bast fibers amalgamate into bundles that are very long (Cherney and Small, 2016).

While there are several potential intentionally grown farm fibers, hemp was chosen for the FMM because of several important characteristics:

- Fiber length. Hemp bast fiber length averages 25 mm and ranges from 5 to 55 mm. The bast fibers are positioned along the outside of the stalk. The inner core, or hurd, fibers have an average length of 0.5–0.8 mm (Han, 1998). In comparison, the average softwood and hardwood fiber lengths are 3.67 and 1.3 mm respectively (Forest Products Laboratory, 1953).
- Low lignin content. Hemp’s low lignin content (3%) makes it valuable for papermaking (Han, 1998).
- Wide geographic range. In 2018, hemp was being grown in 19 states totaling 25,541 acres (10,336 ha) that are for the purposes of the sale of fiber, grain and seed, mostly in a research context. The largest market for hemp products is for cannabidiol (CBD) extracts which are being sold for medical purposes (Johnson, 2018).
- Yields. A survey of reported per acre yields in North America and Europe found an average of 3.7 tonnes/acre (9.1 tonnes/ha) of plant material (Kerr, 2018).
- Potential in building products. Cherney and Small (2016) note: “From a building materials standpoint, hemp and other natural fibers have light weight, high strength to weight ratio, high insulating potential, and are more recyclable than conventional materials.”

The Fiber Migration Model

The fiber migration model (FFM) was developed to simulate the migration of US fiber production from forests to farms (Kerr, 2018). FMM is in two parts:

- substituting forest fiber with farm fiber (Part 1); and
- converting private timberland to public forestland (Part 2).

Both are necessary to fully achieve full conservation and restoration of forestlands to optimally provide for NRMES.

Part 1: Substituting Forest Fiber With Farm Fiber

Major modeling steps

- The dry weights of US wood products by major categories were determined (UN Food and Agriculture Organization, 2018).
- Potentially available farm fiber (existing byproducts and potential intentional fiber crops) were analyzed (Langholtz et al., 2016).
- Estimates were made as to the achievable substitution of forest fiber with farm fiber: pulp and paper (95%), wood-based engineered products (75%), sawnwood (50%).
- Estimates were made as to how much of the substituted farm fiber would come from existing agricultural byproducts (60%) and from intentionally grown fiber crops (40%). Intentionally grown crops have longer fibers than existing agricultural waste fibers, necessary for adding strength to construction and some paper products.

Fig. 9 The outer bast fiber on a stalk of hemp. Wikipedia Commons. Released into the public domain.

Key findings

- 78% of US fiber from forests could effectively be substituted with farm fiber.
- 32.2 million acres (13 million ha), or 9.5% of US cropland (340 million acres [138 million ha]) would have to be dedicated to hemp cultivation.

Part 2: Converting Private Timberland to Public Forestland

Private forestlands should be converted to public forestlands for two major reasons. First, to secure the provision for this and future generations of the multiple NRMES of forestlands, the lands should be in public ownership. Second, as most US fiber production migrates from forest to farm, the market value of private timberland will decrease significantly. This will result in stranded investments for industrial timberland owners and a reduction of net worth for private timberland owners. As the fiber migration would be a result of directed government policy it is appropriate to compensate affected private forestland owners, as well as affected local and state governments, and displaced forest and mill workers.

Major migration steps

- Determine the average fair market value of US forestland (\$1823/acre [\$4505/ha]) and the amount of private timber to be converted to public forestland (78%; the result from Part 1), and determine a timeframe for the migration (20 years). Though a relatively rapid transition time, two decades was chosen because of the vital need for rapid and dramatic action to avoid the worst of climate change, during which the world must limit the increase in global temperature to no $> 1.5^{\circ}\text{C}$ (Allen et al., 2018).
- Determine a source of revenue to fund the transition. The FMM analyzed two options to raise the revenues necessary to carry out the migration of most US fiber production from forests to farms over a 20-year migration period:
 - increasing the motor fuel tax on gasoline and diesel by \$0.42/gal; or
 - tax carbon emissions at a rate of \$13.13/t CO₂e

(For comparison, the average combined local, state and federal motor fuel tax in the US per gallon of gasoline and diesel is \$0.5249 and \$0.6051 respectively (American Petroleum Institute, 2018). Three Republican members of the US House of Representatives have introduced a bill that would tax emissions at \$24/tonne CO₂e (Curbelo, 2018) and a group of distinguished Republican conservatives have proposed a \$40/t CO₂e tax (Baker et al., 2017). Of course, to adequately address climate change, any tax on carbon needs to be significantly higher than \$13.13/tonne CO₂e (Carr, 2018).)

- Provide for not only fair market value compensation to affected landowners, but also:
 - (1) assist affected state and local governments;
 - (2) assist forest workers displaced by the transition;
 - (3) provide an endowment fund for the ongoing operational costs of managing the again public forestland; and
 - (4) and cover overhead costs of acquisition.

Key findings

- 8 million acres per year of private timberland could be converted to public forestland over a 20-year period (280 million acres, 112 million hectares) at an average cost of \$1823/acre (\$4504/ha), or \$510 billion total.
- An additional 25% of the average per-acre cost (\$456 [\$1127/ha]) would be provided to cover overhead costs of acquisition.
- An additional 100% of the average per-acre cost (\$1823/acre [\$902/ha]) would endow a fund to pay for annual operations, which if invested at 5% would yield \$91/acre/year (\$225/ha/year). The cost of managing federal public forestlands in western Oregon ranges between \$24/ and \$86/acre (\$59/ and \$213/ha) in 2018 dollars (Kerr, 2012a).
- An additional 100% of the average per-acre cost (\$1823/acre [\$902/ha]) would be given to state and local government to offset lost tax revenues, which if invested at 5% would yield \$91/acre/year (\$225/ha/year). Since such governments barely tax private timberland (Greaves, 2009; Kerr, 2012b, c), this will result in more revenues to affected governments than by continuing to tax them.
- An additional 10% of the average per-acre cost (\$182/acre [\$450/ha]) would be placed in a fund to compensate displaced forest and mill workers, which would result in them receiving 10 years of their average median wage.

The 20-year migration timeframe was chosen to allow for an efficient economic and less stressful social transition resulting from moving most US fiber production from forest to farm.

Who Would Manage the Forests?

Private timberlands converted to public forestlands will need to be managed by an appropriate public agency. There are multiple agencies, at the federal, state and local level that are suited for the task.

The four major federal land management agencies are the Bureau of Land Management (BLM), Fish and Wildlife Service, Forest Service, and National Park Service. There are large amounts of generally forested private forestlands that are inholdings within the boundaries of the units of the National Forest System, National Park System, National Wildlife Refuge System, and BLM's National Landscape Conservation System and other BLM holdings. For example, only 54% of the lands within the official boundaries of eastern national forests are federal public lands. Nationally, only 83% of the lands within the boundaries of the National Forest System is Forest Service-owned (Kerr, 2017). Besides rounding out existing conservation system units, entire new conservation units could be established with the converted forestlands.

At the state level, there could be many more and expanded state parks, forests, wildlife areas, and recreation areas. At the local level there could be many more and expanded county and city forests and parks, as well as surface drinking watershed protection areas.

Surface Water Protection

Americans use 198 billion gallons per day of freshwater drawn from surface sources. 70% of all fresh water use is from surface sources. 61% of public water supplies (residential, commercial and industrial) come from surface-water sources (Dieter et al., 2018). 53% of surface water watersheds are forestland (Oswalt and Smith, 2014). 68% of Americans use public water systems that are supplied by surface water. As the Centers for Disease Control (2018) notes, "Even though most community drinking water (especially from surface water sources) is treated before entering the home, the cost of this treatment and the risks to public health can be reduced by protecting source water from contamination."

Most surface water sources are not managed to protect water quality and quantity values. Private forestlands in municipal watersheds could be acquired to protect surface drinking water quality and quantity.

Deed Stipulations

As the purposes of the newly acquired public lands is the secured and continuous provision of NRMES, (e.g. the conservation and restoration of biological diversity, the protection of water quality and quantity, the sequestration and storage of carbon, and the provision of compatible recreation), it is important the lands are managed as such.

All transfers of deed to the receiving public agency should have a provision that restricts incompatible uses. The deed should also include reversionary or diversionary clause so that if the managing agency violates the terms, the forestland is transferred to another public agency. Finally, the managing agency would have to agree to be citizen-suit judicial enforcement of the agreement.

Some surface drinking water sources are protected by law. New York City's water supply in the Adirondack Mountains of upstate New York is constitutionally protected. Article XIV of the New York Constitution requires that "The lands of the state, now owned or hereafter acquired, constituting the forest preserve as now fixed by law, shall be forever kept as wild forest lands. They shall not be leased, sold or exchanged, or be taken by any corporation, public or private, nor shall the timber thereon be sold, removed or destroyed" (New York Department of Environmental Conservation, 2018).

Policy Changes Necessary to Migrate US Fiber Production to Farm From Forest

Expressions of consumer demand can also be channeled through the political process by voters (all of which are consumers) to demand action by their elected officials. Thus, the federal government could encourage the migration of US fiber production from forests to farms by:

- Redirecting a portion of farm subsidy programs away from the major commodity crops (corn, wheat and soybeans, etc.) toward intentional fiber crops and the utilization of agricultural waste fibers.
- Eliminating subsidies to timber production in the federal tax code (Landy, 2012; Kerr, 2012d)—if not also redirecting them toward farm fiber.
- Ending subsidies to the timber industry from the sale of timber on federal public forestlands (Taxpayers for Common Sense, 2016)—if not also redirecting them toward farm fiber.
- Impose a price on the emission of carbon into the atmosphere (World Bank, 2016) not only by fossil fuel extraction from underground, but also by fiber extraction from forests. Carbon dioxide emitted from either the burning of fossil fuels or harvest of forest fiber are indistinguishable to the atmosphere.

State and local governments could similarly impose a price on atmospheric carbon emissions and end their general practices of taxing forestland at below market values (Greaves, 2009; Kerr, 2012b, c).

Aspects and Impacts of a US Fiber Transition From Forests to Farms

Moving US fiber production from forest to farm will have environmental, economic and social impacts, both positive and negative. The FMM mitigates most of the major negative impacts.

Climate

Adding value to waste fibers mean less field burning of agricultural crop wastes with resultant CO₂ emissions to the atmosphere. Intentional fiber as an additional rotation crop will also tend to decrease CO₂ emissions, as well as nitrous oxide (N₂O) emissions from farming (Behnke et al., 2018; King and Blesh, 2018). N₂O is a greenhouse gas with a global warming potential 298 times that of CO₂ (Environmental Protection Agency, 2018).

The most significant effect would be the reduction of carbon emissions and the additional sequestration and storage that would result from ending logging on approximately fourth-fifths of US private timberlands. The FMM (based on Harris et al., 2016; Le Quéré et al., 2018) estimates that during the 20-year fiber migration period and the following 30 years of, that ~11.3 gigatonnes of US CO₂e emissions to the atmosphere due to logging would be avoided, equivalent to is ~2 times US 2016 emissions (Environmental Protection Agency, 2018). These avoided emissions mean that global CO₂ levels would not increase ~6.5 ppm. To avoid the worst of climate change, the world must limit the increase in global temperature to no more than 1.5 °C (Allen et al., 2018). As the forestlands grows—and are no longer logged—the greater the probability of meeting the <1.5 °C necessity.

Forests

NRMES—including but not limited to carbon storage and sequestration, biological diversity, ecosystem function, watershed integrity, and aesthetic values—would increase as logging ended on lands and are converted from private timberlands to public forestlands.

It is a well-established principle of the science of conservation biology that to have a functioning ecosystem, both across the landscape and over time, between one-quarter and three-quarters of that ecosystem must be conserved (Wilson, 2016). If the migration of US fiber from forest to farm does occur as modeled, 92% of US forestlands would be in public ownership, with most of it managed primarily for the provision of NRMES. Given the imperatives of also removing excess carbon from the atmosphere, and providing for clean and plentiful drinking water and other NRMES, the large percentage is ecologically, economically and socially justified.

Private Forestland Owners

There are two major categories of private timberland owners: industrial and nonindustrial. As the FMM would provide for fair market value compensation to willing sellers, industrial timberland owners would have their land and standing timber assets liquidated and would invest the funds in other investments, perhaps more lucrative ones. Much nonindustrial timberlands are held by owners who also have the goal of profit maximization, so they are similar to industrial timberland owners. Other nonindustrial private forestland owners may sell their lands for public ownership, perhaps reserving small amounts for a home. They may decide to keep their forestland, even though its market value has decreased as there would no longer be a market for fiber extraction. In other cases, current nonindustrial private timberland owners will decide to keep their forestland, but their heirs may decide to sell.

Forest Workers

The fiber migration model predicts that ~156,000 jobs (78% of 2017 workers) would be lost as US fiber production migrates from forest to farm over the course of 20 years. The FMM would compensate displaced workers with 10 years of wages. Some workers will choose to retire, others might improve their education to help find employment in other occupations, immediately find a new job, pay off debt, invest for retirement, etc.

Forest Fiber Processing Facilities

US fiber production, now centered on forests, especially in the Pacific Northwest and the South, will migrate to the Midwest, where there are plentiful agricultural waste fibers and opportunities to insert intentional fiber crops into farmland rotations. The transition of US fiber production from forests to farms will have dramatic effects on industries that manufacture paper and construction products. There will be winners and losers. However, the FMM's projected US fiber migration from forests to farms of 20 years is long enough for the owners of existing forest fiber processing facilities to fully amortize their investments. Some forest-fiber processing facilities could convert to farm fibers because they are located near farm sources of fiber. This includes much of the South where farms and forests are more interspersed than elsewhere in the US and where most US pulp and paper manufacturing facilities are located (Stritholt, 2008). This also includes some pulp and paper facilities in Oregon's Willamette Valley located near ryegrass fields.

Food

In modeling the utilization of a ~1 billion tonnes of US farm fiber for bioenergy production annually, the USDOE report says the change to farmland allocation will not affect the food supply, either for fruits and vegetables directly consumed by humans, or for feed consumed by livestock (Langholtz et al., 2016).

Farms

In general, rotation of crops improves productivity (Behnke et al., 2018). Integrating profitable intentional fiber crops into rotation can improve soil organic carbon, which means increased farm productivity and sustainability.

Farmers

As value is added to waste fiber from existing crops that is now burned or otherwise disposed of and new profitable intentional fiber crops are introduced in rotation, farming will tend to become more profitable and sustainable.

State and Local Governments

The FMM provides for compensation to governments for loss of tax revenues equal to the market value of affected private forestland. If state and local government would invest those funds, an endowment would be created with annual revenues in excess of what the governments now receive in taxes.

Bioenergy Versus Fiber Production

In 2017, 38.1 million acres (15 million ha), or one-tenth of US farmland was dedicated to ethanol (from the sugar in corn kernels) and biodiesel (from the oil in soybeans) (Merrill and Leatherby, 2018). Current biofuel production does not conflict with fiber and in fact produces a lot of waste fiber. The US Department of Energy has a different vision for most farm fiber biomass: cellulosic ethanol (US Department of Energy, 2018). The FMM has a vision for farm fiber: paper and construction products in lieu of wood. These visions are generally incompatible. Both visions have challenges. Challenges for cellulosic ethanol, which uses extremely fibrous feedstock, are primarily that it is not presently, in the absence of a large subsidy, profitable with current technologies (Hirtzer and Renshaw, 2017). Yet efforts to commercialize cellulosic ethanol continue (Environmental and Energy Study Institute, 2017). Cellulosic ethanol may turn out not be able to compete as a liquid transportation fuel, especially if the US transportation fleet (automobiles, delivery trucks and tractor trailers) continues toward electrification (Bloomberg New Energy Finance, 2017; Heid et al., 2017).

If not rolled back, achievable US fuel efficiency standards for passenger cars, light trucks (Plumer and Popovich, 2018), and heavy trucks (Vlasic, 2016) can dramatically reduce demand of both fossil fuels and farm fuels. As farm fiber production increases, the prices, supplies and demands for farm fuel can adjust, often though efficiency gains that need not materially affect prices.

Food Versus Fuel Versus Fiber Fight?

The United States land area is 1.9 billion acres (0.8 billion ha), 392.7 million acres (158.9 million ha) of which is cropland (Table 8). The FMM finds that ~10% of US farmland currently in production (neither idle nor fallow) would have to be dedicated to intentional fiber production to migrate most US fiber production from forests to farms.

As demand for farmed fiber increases, will it be met at the expense of farmed food? USDOE say food production will not be affected by utilizing agricultural wastes and growing intentional fibers for fuels (Langholtz et al., 2016). Such would also be the case if the fiber were used for paper and construction products. But what if food and fiber from farms does conflict?

Increasing farm fiber production need not come at the expense of the nation's fuel or food supplies, as current food and fuel consumption practices are quite wasteful and inefficient. Great gains could be made in response to competing demands for farmland that would tend to increase food prices. For example, 133 billion pounds (59.4 billion kg) or 31% of the nation's 430 billion pounds (195 billion kg) of food produced in 2010, with a retail value of \$162 billion, was thrown away uneaten at the retail and

Table 8 Cropland use in the United States.

<i>Cropland use</i>	<i>Million acres</i>	<i>Million hectares</i>	<i>Percentage</i>
Livestock feed	127.4	51.6	32%
Food we eat	77.3	31.3	20%
Other grain and feed exports	62.8	25.4	16%
Idle/fallow	52.0	21.0	13%
Ethanol, biodiesel	38.1	15.4	10%
Wheat exports	21.5	8.7	5%
Cotton	13.6	5.5	3%
Total	392.7	158.9	100%
Total not idle/fallow	340.7	137.9	—

Merrill, D and Leatherby, L (2018) Here's how America uses its land. New York, NY: Bloomberg.

consumer levels (Buzby et al., 2014). This does not include losses at the point of production on farms (e.g. fruits and vegetables with imperfect-color and/or -shapes).

If the price of red meat (produced from the one-third of cropland dedicated to livestock feed) increases due to competition of land for forage or fiber, consumption will likely decrease as would greenhouse gas (GHG) emissions. Reducing red meat consumption lowers the risk of dying from eight major diseases by 26% (Etemadi et al., 2017). Animal agriculture contributes between 10% and 25% of total global GHG (higher figure includes deforestation and other land use changes). GHG emissions from beef are orders of magnitude more than other meats. The consumption of 2.2 pounds (1 kg) of beef is equivalent to driving an automobile 99 miles (160 km) (Schwarzer, 2012).

Conclusion

The vast and irreplaceable array of NRMES provided by US forestlands demand that most of such lands no longer be managed for fiber production, but for conservation. It is technically feasible to meet US fiber demand from mostly nonwood plant fibers. With changes in government policy and in consumer demand, US fiber industries can be profitably transformed for the benefit of forestlands, farmlands, the climate, and society.

“All models are wrong, but some are useful” (Box and Draper, 1987). This article outlines a method and presents a very simple model of how to migrate US fiber production from forests to farms. This fiber migration model (FMM) does not consider many variables including, but not limited to, increases or decreases in (1) fiber consumption, (2) fiber recycling, (3) forestland prices, (4) farming costs, (5) population, and many other factors that should be included in further analyses.

Criticism of and suggestions for the model are very welcome. However, it may more the intent and direction of the model—moving most US fiber production from forests to farms—rather than the specifics that is most bothersome to the critic.

The fiber migration model assumes a direct path without diversions, dead-ends and setbacks, or political opposition from vested interests. All will undoubtedly occur, but all can be overcome.

“If you have built castles in the air, your work need not be lost;
that is where they should be. Now put the foundations under them.” Henry David Thoreau, *Walden* (1854).

Abstract

As the world seeks solutions to climate change, and in light of the 2015 Paris Climate Agreement, attempts to decarbonize the electric power sector by 2050, a primitive form of energy generation has reemerged as a possible environmentally-friendly solution to fossil fuels. Bioenergy, defined here as the process of turning woody plant based matter into a combustible fuel used in the electric power generation sector, is perhaps the oldest source of energy that humans have known. While bioenergy has been branded as an environmentally-sound solution to the problems of electric power sector decarbonization and climate change, there are a number of issues with an increased global dependence on bioenergy as a replacement for fossil fuels.

This article details the current trends in bioenergy in the United States and globally, with a focus on the European Union. We detail why there has been an increased interest and demand for bioenergy as a substitute for fossil fuels in the electricity sector. Then, we examine the climate impacts of burning forests as fuel. Finally, we document the troubling ecological impacts of increased bioenergy production, alongside some of the troubling human community impacts that arise as a result of bioenergy harvesting, logging, processing, and shipping.

Introduction

As the world seeks solutions to climate change, and in light of the 2015 Paris Climate Agreement, attempts to decarbonize the electric power sector by 2050, a primitive form of energy generation has reemerged as a possible environmentally-friendly solution to fossil fuels. Bioenergy, defined here as the process of turning woody plant based matter into a combustible fuel used in the electric power generation sector, is perhaps the oldest source of energy that humans have known. Bioenergy is an energy-lite resource (8262 Btu/lbs), compared to fossil fuels such as coal (9507 Btu/lbs) and natural gas (19,000 Btu/lbs), meaning that it requires more mass to generate an equivalent amount of electricity ([U.S. Energy Information Administration \(EIA\), 2019b](#)).

Humans have been turning trees and other woody material into burnable fuels to heat our homes and cook our food for thousands of years. Like all combustion-based technologies, wood-based bioenergy (referred to alternatively as bioenergy, biomass, or wood pellets herein) has direct and potentially significant impacts to surrounding air quality through the release of local air

pollutants, as well as carbon dioxide as a result of the combustion process. In addition, there are a number of local hydrological, ecological, and biodiversity impacts to ecosystems from which bioenergy is harvested. While bioenergy has been branded as an environmentally-sound solution to the problems of electric power sector decarbonization and climate change, there are a number of issues with an increased global dependence on bioenergy as a replacement for fossil fuels (Drax Group PLC, 2019).

We detail the current trends in bioenergy development in the United States and globally, with a focus on the European Union (EU), and why there has been an increased interest and demand for bioenergy as a substitute for fossil fuels in the electricity sector. Then, we examine the climate impacts of burning forests as fuel and why this will not help us turn back the rising threat of climate change nor avoid the need to invest in truly renewable energy solutions. We further discuss the troubling ecological impacts of increased bioenergy production, alongside some of the troubling human community impacts that arise as a result of bioenergy harvesting, logging, processing, and shipping. Finally, we highlight a number of environmental justice impacts, primarily within the southeastern United States, as a result of an increasing reliance of bioenergy.

Current Trends in Bioenergy Production and Demand: US and Globally

In the developed world, prior to the emergence of bioenergy as a possible substitute for fossil fuels in the electric power generation sector, bioenergy was and is still widely used in the residential home heating sector. According to the US Energy Information Administration's (EIA) 2015 residential energy survey, wood burning stoves are the primary source of heating for 3.5 million US households (roughly 3% of all households) and the secondary source of heating for 9.2 million households (U.S. Energy Information Administration (EIA), 2019a). In the European Union, an estimated 40% of all wood consumed in 2015 was in the residential heating sector, representing the largest portion of bioenergy consumption (Birdlife, FERN, and Transport and Environment, 2017). However, over the last 15 years, there has been a marked increase in the use of bioenergy in the non-residential sector, in order to produce electricity and thermal energy for commercial and industrial processes. According to the EIA, biomass electricity generation increased 18% between 2005 and 2015, with biomass accounting for almost 1% of all US electricity generation. In 2018, it accounted for around 0.5% of all US electricity generation (U.S. Energy Information Administration (EIA), 2019b) (Fig. 1).

While in the United States, the role of bioenergy in the electric power sector remains small, it has ballooned in the European Union (EU). Over 44% of renewable energy in the EU comes from bioenergy or waste wood, with bioenergy accounting for 7.5% of EU-wide gross final energy consumption in 2016 (Brack et al., 2018). EU demand for bioenergy is substantial and growing, and while European nations are able to produce a significant amount of bioenergy, it is not enough to meet regional demand.

Much of this growth in European demand for bioenergy is being met by increasing global imports. In 2016, it is estimated that 40% of overall wood pellet consumption in the EU was from imports. (Brack et al., 2018) In the United States, bioenergy export production and capacity has increased rapidly over the last few years. In 2012, the United States exported 1.9 million metric tonnes of densified biomass fuel. By 2018, that number had jumped to 6.1 million metric tonnes, more than a 300% increase in just 6 years (U.S. Census Bureau, 2019) (Fig. 2).

The southeastern United States has been the largest source of this expanded global demand for biomass fuels, and each pellet-producing mill has a 120 km sourcing radius (Fig. 3). Since 2012, the US Southeast has been responsible for over 98% of wood pellet exports. This demand eclipses pre-existing demand for other forest products, primarily pulpwood, from the region. From 2012 to 2015, pulpwood generation in the US Southeast decreased by 6.8 million metric tonnes, about 4.5%; in the same time period, the equivalent amount of wood pellet production increased by 5.6 million metric tonnes, or 249% (Table 1). Although

Fig. 1 Electricity (million kilowatt hours) generated from wood, 2000–2018, in the United States.

Fig. 2 Wood pellet exports from the United States, 2012–2018. Exports tripled in just 6 years, with nearly all wood pellets (>98%) coming from the US Southeast.

Fig. 3 The locations and operating capacities of current pellet production facilities in the United States.

the demand for bioenergy still represents a relatively small portion of the pulpwood market in the United States, it is growing steadily and may present supply problems in the near future for non-wood pellet US forest products companies. (See [Table 1](#)).

Policy Drivers of Bioenergy Demand

Much of the increased demand for densified bioenergy fuel results from recent changes in international and national policies. We identify two potential reasons for the increased reliance on bioenergy in the electric power sector around the world. First, the rise in global demand for bioenergy has been spurred by a number of national and international climate and energy policies aimed at

Table 1 Pulpwood and Wood Pellet production, 2012–15, US Southeast.

<i>Year</i>	<i>Pulpwood, Green Tonnes</i>	<i>Wood Pellets, Green Tonnes</i>
2012	153,591,595	3,730,472
2013	151,816,980	5,711,590
2014	149,411,769	7,981,178
2015	146,740,931	9,289,367
% Change	4.46%	249.01%
Total change	–6,850,664	5,558,896

Pulpwood green tons retrieved from (Gray et al., 2016) and previous years of reports, converted to metric tonnes. Wood pellet dry tons retrieved from (U.S. Census Bureau, 2019) and converted to green metric tonnes, assuming a standard 50% water content.

encouraging a low-carbon transition and tackling climate change. Second, some countries, such as the United Kingdom subsidize bioenergy use as an alternative to fossil fuels. And finally, subsidizing existing coal-fired powered plants to burn bioenergy is a political win because transforming coal-fired power plants to co-firing plants is a fairly easy process that extends the useful life of an otherwise stranded generation asset.

National and International Climate and Energy Drivers

First, worldwide climate treaties have created perverse incentives to rely on bioenergy to meet climate goals. International climate treaties like the 1997 Kyoto Protocol establish that carbon emissions from direct combustion (excluding harvest, production and transportation of woody material) are counted under the country of origin's Land Use/Land Use Change (LULUC) emissions category (Grubb et al., 1997). However, the United States never ratified the Kyoto Protocol, meaning that bioenergy exported from the US to other countries is not subject to the accounting procedures demanded by the Kyoto Protocol (Hovi et al., 2003). In practice, this means that imports from North America to countries that are parties to the Kyoto Protocol, treaty countries, such as the European Union, are considered “carbon neutral” by the Kyoto Protocol without accounting for the carbon emissions from the combustion process anywhere within the accounting system. This accounting loophole has created a perverse incentive for treaty countries to import bioenergy from non-treaty countries and only account for a fraction of the associated carbon emissions. In addition, the European Union, which established a renewable energy target of 20% by 2020 in 2009 and increased it to 32% by 2030, classifies most woody bioenergy as carbon neutral (Klessmann et al., 2011).

Fuel Switching and Existing Infrastructure

With large and increasing renewable energy targets, countries subject to those targets must consider the cost and extent of switching from coal and other fossil fuels to renewable energies. With many operational coal power plants being potentially phased out in favor of renewable and low carbon energy production options, there has been continued interest in repurposing coal power plants through either co-firing biomass with coal, or conversion to complete biomass combustion (Demirbaş, 2003; Hughes, 2000). In contrast to other renewable energies, biomass presents an opportunity to reuse or improve existing infrastructure instead of needing to build new plants, windmills, or solar panel fields. As a result, many countries party to renewable energy goals, like the Kyoto Protocol, have promoted the use of bioenergy through subsidies and credits.

National Subsidies and Support for Bioenergy

In planning for climate change mitigation, many countries created pathways that rely heavily on the adoption of bioenergy as a pathway to transition away from fossil fuels. As a result, several countries have created substantial subsidy programs to encourage the adoption of co-firing biomass with coal, or transitioning coal-powered plants entirely to wood pellet fuel. In 2012, 12 EU member countries contributed 8.3 billion Euros (9.4 billion USD) in subsidies to biomass usage (Alberici et al., 2014) (Fig. 4).

In the United Kingdom (UK), the largest importer of US wood pellets, renewable energy from biomass and other sources is subsidized through the Renewable Obligation Certificates system, where the government rewards companies with credits for producing renewable energy, which can then be sold to energy delivery companies. The UK's largest power producer, Drax, reported 468 million pounds in profits from Renewable Obligation Certificates, equivalent to just over 593 million USD in 2018 (Drax Group PLC, 2019).

As the use and subsidization of bioenergy rises rapidly in the international economy, many scientists have expressed worry about the longevity and feasibility of bioenergy as a widely adopted renewable technology (Duffy et al., 2016; Editorial Board, 2016; Söderberg and Eckerberg, 2013). There are potentially major impacts to forest biodiversity, resilience, ecosystem services, and carbon balance, as well as impacts to air and water quality, equity, and quality of life in nearby human communities.

Subsidies and costs of EU energy. European Commission.

Climate Impacts of Forests as Fuel

The extraction of timber for wood pellet production creates direct and indirect greenhouse gas (GHG) emissions into the atmosphere. GHG emissions come not only from pellet burning, but also from the production and transportation processes as well. Furthermore, forest operations can impact soils, altering physical, biological, and chemical properties due to the use of agrochemicals, heavy machinery, and the correlated requirements of lubricants and fuels (Cambi et al., 2015). A suitable way to evaluate the environmental performance and climate impact of the wood pellet industry in terms of pollutant emissions and energy consumptions is through a life cycle assessment (LCA) (see Fig. 5). LCAs assess the extraction and consumption of resources including GHG emissions throughout the entire lifecycle of production extraction and creation (Campbell et al., 2011).

Comparing GWP From Bioenergy to Other Renewable Energies

With many possible GHG emissions from different chemical compounds, it is often necessary to standardize the impact of those chemicals on the global carbon cycle. The Global Warming Potential (GWP), defined by the U.S. Environmental Protection Agency (EPA) as a measure of how much energy the emissions of 1 t of a greenhouse gas will absorb over a given period of time (commonly 100 years), relative to the emissions of 1 t of carbon dioxide (CO₂), is one such measure (Environmental Protection Agency, 2017). This potential depends on the radiative efficiency of the gaseous species and its atmospheric lifetime.

A study conducted in British Columbia, Canada found that the GWP for the production of wood pellets and overseas transportation is 723 kg CO₂ e/t or 0.15 kg CO₂ e/KWh of wood pellets when using natural gas as fuel, and 532 kg CO₂ e/t or 0.11 kg CO₂ e/KWh when using sawdust as fuel in the production process, with an additional 916 kg CO₂ e/t, or 0.19 CO₂ e/KWh stored in the wood and combusted during electricity generation (Magelli et al., 2009) (Because this paper produced numbers by tonne instead of kilowatts, there is some conversion that needs to take place in order to compare between technologies. We estimate that there are 4800 KWh per tonne of wood pellets, and divided accordingly.). Together, this means a GWP range of 0.30–0.34 kg CO₂ e/KWh for wood pellet electricity generation, assuming combustion at 100% efficiency. However, electricity generation from biomass fuel combustion is still only 20–25% efficient (Biomass Energy Resource Center, 2009), and so a final, more realistic calculation would be 1.35–1.53 kg CO₂ e/KWh for wood pellet electricity generation.

On the other hand, similar LCA studies for wind turbines reported GWP values of approximately 0.06 kg of CO₂ e/KWh (Bayindir et al., 2018) and 0.029 kg of CO₂ e/KWh (Tazi et al., 2018). A study made on photovoltaic power systems used in the production of solar energy assets GWP values of 1 kg of CO₂ e/KWh (Frischknecht et al., 2015). In terms of GWP, both photovoltaic power systems (solar) and wind turbines have lower GWP than wood pellets used to generate electricity.

In 2018, the United States exported 6 million metric tonnes of wood pellets which likely released approximately 9 million tonnes of CO₂ e into the atmosphere. If industries continue to invest aggressively in bioenergy and the demand increases by 20% (conservative, based on previous years' expansion rates), in the next 5 years, carbon released into the atmosphere from wood pellet consumption could rise to 22 million metric tonnes of CO₂ e per annum, equivalent to an addition 4.7 million vehicles on the road each year.

Fig. 5 A model Life Cycle Analysis for wood pellet production. It displays the system boundaries, identifying the different processing stages involved in the LCA for wood pellet production. Additionally, it includes the types of energy used and the emissions associated with the production and transportation.

The Inaccuracies and Assumptions of Carbon Neutrality

Many analyses of wood pellet GHG emissions automatically exclude the carbon stored in the fuel (former trees) itself (Brack et al., 2018; Hoefnagels et al., 2014; Magelli et al., 2009). This is based on the net-growth theory—in short, that because forests are continuing to grow in a given region (predominantly the US Southeast), one can assume that the landscape is automatically absorbing new carbon to replace the carbon in wood pellets that will be burned internationally. Although this is both simple and convenient, this net-growth theory fails to account for the lost growth potential of acres harvested for bioenergy. That is, regional acres will continue to grow whether or not bioenergy harvests occur. There is no additionality to replace the carbon lost during bioenergy harvest.

Instead, consider the acres on which the bioenergy harvest occurs. After harvest there will be a “carbon debt” (C Debt) on those acres until they regrow enough to restore the carbon lost during harvest, and exceed the carbon benefits from previous fossil-fuel based power generation (Mitchell et al., 2012; Walker et al., 2010). Estimates of carbon debt vary widely and are based on variables that primarily include the type of harvest (tops and limbs, large residues, or whole trees) and pre-existing land cover (natural or artificial stands). One study indicates that even just removing harvest residues (tops, limbs) from a harvested site can reduce the mitigation potential by 10–40% (Zanchi et al., 2010). Modeling a coal plant conversion to wood pellets in Ontario, Canada revealed that the carbon debt repayment for their source would not occur until a full 91 years after operation if harvesting specifically for bioenergy (Ter-Mikaelian et al., 2015). The oft-termed “Manomet study” reveals a carbon debt repayment period between 20 and 90 years (Walker et al., 2010). Finally, if a natural forest is replaced with a plantation for bioenergy, carbon debt repayment may take 150–200 years (Zanchi et al., 2010).

The Reality of Bioenergy Production in the US

Carbon debt repayment and GHG emission estimates often make assumptions about the source of wood for pellets that may be inaccurate in the lived reality of the wood pellet market. For example, when studies consider only small residues harvested additionally from sites where other forest products are being sourced from, their relative impact is small (Walker et al., 2010; Zanchi et al., 2010). However, in practice, a large portion of harvested materials in the United States for bioenergy production comes from whole trees and large residues. The standard harvest method in the United States, and especially the US Southeast, is clearcutting. The best wood may go to lumber production, but the bulk of it will go to pulpwood production: paper products and wood pellets.

Enviva, the largest US-based wood pellet export company, reports that < 18% of their input material is from “Sawdust, shavings, residuals from wood manufacturing, or arboricultural sources” (Enviva, 2017). The remaining 82% of input material comes from pine plantations (38%), mixed pine and hardwood forests (40%), and other hardwood forests (5%). Under current conditions, carbon debt repayment is on a timescale much longer than the time currently available to address carbon emissions and prevent the worst impacts of climate change from occurring. Finally, these practices contribute to wide scale impacts on the carbon balance of forests in the US Southeast and nationally.

Ecological Impacts of Forests as Fuel

There are many similarities between traditional forest harvest and forest harvest for bioenergy. As a result, it is necessary to discuss the general impacts of anthropogenic forest disturbance through forest harvest, as well as the additional impacts that demand for bioenergy has brought into natural ecosystems.

Impacts of Harvest on Forest Ecosystems

The United States leads in forest harvest rates

The US, and predominantly the US Southeast, is the second largest producer of pulp and paper products in the world (Food and Agriculture Organization, 2018). As a result, the US Southeast has one of the highest forest turnover rates in the world, four times higher than the rate of South American rainforests (Hansen et al., 2013). Less than half of the forest stands in the US Southeast are older than 40 years (Oswalt et al., 2014).

Impacts on carbon balance of US forests

Although forests in the United States are considered a net sink, not a net source of carbon, this was not always the case. Widespread logging from the 1700 to 1935 released 42,000 Tg (4.2 billion metric tonnes) of carbon into the atmosphere. From 1935 to 2010, just 15,000 Tg (1.5 billion metric tonnes) had been recovered by US forests (McKinley et al., 2011).

Despite current successes in net growth of US forests, modern forest harvests still significantly reduce the growth rate of the terrestrial carbon sink. A joint study between scientists at nonprofit institutions and the US Forest Service revealed that forest harvest activities account for 85% of the carbon emissions from US forests, more than insects, drought, disease, wind, and conversion combined (Harris et al., 2016).

Impacts on rare species

Forest harvest also reduces the frequency of valuable habitat for rare species. The Fish & Wildlife Service found that 56% of all wetland losses in the United States from 2004 to 2009 were attributable to silvicultural activities (Dahl, 2011). Wetlands and wetland forests in particular are reserves of remarkable biodiversity (Junk et al., 2006; Thiere et al., 2009).

Logging activities can impact biodiversity for decades after a forest harvest occurs. In the Mississippi Alluvial Valley, two species of concern, prothonotary warbler (*Protonotaria citrea*) and Acadian flycatcher (*Empidonax virens*), were impacted by the opening of gaps in the forest canopy from harvest activities, and differences in species composition between stands were found for up to 35 years after a forest harvest (Heltzel and Leberg, 2006). Historically, logging has been implicated in the decline of several species, including *Pieris virginienensis*, a rare butterfly native to the eastern US (Davis and Cipollini, 2016). Additional logging impacts are documented in the Pacific Northwest region of the United States (DellaSala et al., 2015), nationally (Heilman et al. 2002), and across the world (Benkman, 1993; Czech et al., 2000; Mackey et al., 2015).

Impacts on water quality in riparian forest systems

During forest harvest, it is often necessary to install temporary or permanent roads, which include temporary or permanent stream crossings for the transport of equipment and logs. Even temporary stream crossings have impacts on temperature, sediment load, and pH (Aust et al., 2011). Even abandoned roads contribute to sediment loads in forest streams (Reid and Dunne, 1984). Although there are voluntary standards (“Best Management Practices”) to prevent the worst impacts to water quality during forest harvest operations, compliance is not always 100%, and compliance rates during biomass harvest has been documented as significantly less than compliance during traditional forest harvest (Barrett et al., 2016). In addition to sediment, high nitrate runoff has been documented from clearcut and patchcut forests for three to 5 years after the harvesting event (Mupepele and Dormann, 2016).

Logging and salvage activities reduce resilience to extreme events

As climate change increases the frequency of extreme events and natural disasters, the desire to engage in “salvage logging” of disturbed ecosystems increases. Often a highly political or economic move, salvage logging could be a significant source of fuel for bioenergy production in the near future (Lindenmayer et al., 2008). However, evidence tends to show that post-disturbance clearcut logging compacts soils, kills seedlings and shrubs associated with forest renewal, increases fine fuels that aid the spread of fire in wildfire prone habitat, and degrades fish and wildlife habitat (Lindenmayer et al., 2008).

Intensive harvest practices harm soil structure and carbon

Nearly 70% of the biosphere's carbon is stored below the ground, in forest soils, around the world (Karsenty et al., 2003). Global soils hold 2400 Petagrams of carbon, about three times the amount of atmospheric carbon currently warming the planet (Paustian et al., 2016). However, forest harvest and especially intensive forest harvest for biomass damages the soil carbon in forests. One study found that over half of the extractable soil carbon was lost in a temperate forest after clear cutting (Lacroix et al., 2016). A meta-analysis showed that biomass harvests reduce soil carbon 15% more than traditional logging, and soils could lose up to 60% of their carbon sink potential after intensive biomass harvest (Achat et al., 2015).

Additional Impacts of Bioenergy Demand on Forest Ecosystems***Bioenergy impacts more acres than solar photovoltaic fields***

Converting wood energy in to usable electric or thermal energy is also less efficient than solar photovoltaic generation. A 50 MW biomass-only electricity generating station with 55.4% efficiency (5 year average from (U.S. Energy Information Administration (EIA), 2019b)) would produce 242,650 MWh per year in usable electric energy under normal operating circumstances in the United States, and use approximately 6300 acres per year of harvested wood and residues (Phillips, 2016). In contrast, a solar photovoltaic field of equivalent MWh would take up roughly 124 acres. In addition, whereas the solar photovoltaic field has a productive life of 25 years, to produce a comparable amount of energy from forest bioenergy would require annual harvest of thousands of acres each year.

Demand for unmerchantable wood

Wood product processing facilities often have strict specifications for accepting incoming wood products. Trunks that are too large, curved, or hollowed can be rejected in favor of better quality of wood. This unmerchantable wood, e.g., curved or hollowed trunks, is accepted and processed by wood pellet plants, and represent a substantial resource for the forest products industry (Hoefnagels et al., 2014). However, these mostly untapped resources also serve as reserves for both carbon and biodiversity (Davis and Cipollini, 2014; Heltzel and Leberg, 2006; Pacific Northwest Research Station, 2003; Rudolphi et al., 2014). Dead-wood legacies, in particular—the type of unmerchantable wood used for bioenergy—accounts for 20–25% of carbon stores in a forest even 62 years after the initial harvest (Schaedel et al., 2017). Expansion of the forest products industry into previously unharvestable areas means that, across the landscape, forest stand age, and therefore, carbon sequestered, will decrease.

Large increases in bioenergy production could impact food security

The pending impacts of climate change include the potential for food insecurity in light of growing populations, increasing frequency and scale of natural disasters, and changes in water availability (Bohle et al., 1994; Brown and Funk, 2008). In addition to these stressors on arable land, the increasing use of wood pellets for electricity and heat generation represents another market pressure on the availability of land for food. Models demonstrating the possibility of major increases in the use of biomass for electricity generation assume massive increases in efficiency of food production coinciding with subsequent decreases in meat consumption (Strapasson et al., 2017). In the United States, if domestic combustion for electricity begins to increase, the U.S. Energy Information Agency estimates an additional 18% increase in US forest harvest is required for every 1% added to current energy production (Duffy et al., 2016).

Community Impacts of Forests as Fuel

The environmental and health impacts to the communities in which bioenergy wood pellets are logged, harvested, processed, and shipped is significant. In the US Southeast, where the bioenergy economy has grown substantially over the last decade, there are 35 wood pellet facilities with a total annual capacity of 9 million dry tons per year (U.S. Energy Information Administration (EIA), 2019b). Due to the economics of harvesting and transporting whole logs to wood pellet processing facilities, most of the timber harvested to produce wood pellets is sourced within a 120 km radius of a facility, which creates a new and substantial burden on roads within the sourcing radius of the pellet facility (Magelli et al., 2009; NRDC, 2015).

Woody biomass and fossil fuels are often burned on-site at wood pellet processing facilities in order to generate thermal energy to dry and process the pellets, which causes an increase in noise and ambient air pollutants such as volatile organic compounds (VOCs) in the immediate vicinity of the wood pellet plant (Anderson and Powell, 2018). The 21 US wood pellet mills exporting to Europe emit a total of 14,500 t of air pollutants per year, including particulate matter, nitrogen oxides, carbon monoxide, and organic compounds. These plants also release 2.8 million tonnes of GHG emissions annually (Anderson and Powell, 2018).

Wood pellet processing tends to have disproportionate impacts on the communities in which pellet facilities and ports are located. According to the National Association for the Advancement of Colored People (NAACP), African-Americans who live within close proximity to a biomass power plant are more likely than any other racial group in the United States to suffer from increased exposure to smog, asbestos, sulfur dioxide, and other air pollutants (Wilson et al., 2011). Finally, there may be other sources of air and water pollution located in communities that have wood pellet facilities, such as meat and poultry farms, industrial and chemical manufacturing, and rail yards and other transportation infrastructure. For example, one county in North Carolina with

a large wood pellet processing plant is also home to a freight train station, natural gas pipeline, chicken processing facility, and natural-gas fired power plant, all sources of local and global air pollutants (Koester and Davis, 2018).

“Environmental justice” was a term that originated in the 1980s and has its roots in the social-environmental justice struggles in the southeastern US. The famous 1982 PCB contamination case of Warren County, North Carolina, a community that was 84% black with per capita incomes 25% below the state median, represents a quintessential example of environmental justice. This case led many poor people of color to demand that their communities not become dumping grounds for toxic waste and harmful industrial and chemical manufacturing (McGurty, 2007). The communities in which wood pellet production facilities are located also tend to be designated environmental justice communities. One study found that poor (above the state median poverty level) communities of color (over 25% percent nonwhite population) in the US Southeast are 50% more likely to have a wood pellet facility sited in their county than wealthier, majority white counties (Koester and Davis, 2018). This trend illustrates the potential environmental justice concerns at play with the expansion of the bioenergy economy in the United States and the increasing global demand for wood pellets.

One recent example illustrates the community and environmental justice concerns of the growing bioenergy industry in the US Southeast. In Hamlet, North Carolina, Enviva, the world’s largest producer of bioenergy wood pellets, opened a 480,000 t-per-year capacity bioenergy processing facility. Hamlet, NC is in the 70th to 90th percentile for Superfund-site proximity, traffic, ozone, PM 2.5, air toxics and cancer risk (US Environmental Protection Agency, 2014). The median poverty level in Hamlet, NC is 27.3%, 7 percentage-points higher than the state overall (Census of Housing, 2013). The nonwhite population of the Richmond County is 37.5%, roughly 16 percentage points higher than the state average (Census of Housing, 2013). In 2019, Enviva was granted an air quality permit from the state’s Division of Air Quality to increase annual production by 16 percent to 570,000 t of dry pellets annually, and then was subsequently challenged in court by three environmental groups, and agreed to install additional air pollution controls to prevent further harm to the overburdened community (Stone, 2019).

Conclusions

Although bioenergy is a “renewable” energy source, it comes with significant costs and impacts to the global climate situations, as well as regional and local ecological and human community impacts. Bioenergy may have a place in the world’s current energy portfolio, however, it should be limited and phased out as quickly as possible. The lifespan, footprint, and climate impacts of other energies are much more attractive than bioenergy as a renewable fuel source.

Abstract

The State of the World's Forests 2018 advocates forests and its linkage to Sustainable Development Goals (SDGs) as a pathway to sustainable development and provides detailed analysis aimed at capturing the contribution of forests and trees to 28 targets relating to 10 SDGs. The report summarizes key policy implications, highlighting the need to: raise awareness and market the benefits of forests and trees to policy-makers and beyond; engage the private sector; integrate forests with the broader sustainable development agenda; invest in transforming the informal sector to unlock missed development opportunities and improve employment conditions.

State of the World's Forests

The State of the World's Forests (SOFO) report was released by Food and Agriculture Organization (FAO) during the World Forestry Week in July 2018. As the full title of the report suggests the data and information analysis provided in the report are focused toward forests being seen as a pathway to sustainable development and linked to the Sustainable Development Goals (SDGs).

In his foreword, Jose Graziano Da Silva, the FAO Director General says, "*The State of the World's Forests 2018* provides detailed analysis aimed at capturing the contribution of forests and trees to 28 targets relating to 10 SDGs."

Table 1 indicates the full range of impacts that forests and trees have on other crucial areas of sustainable development ranging from poverty eradication, gender equality, access to water and energy to conservation of forests, halting biodiversity loss and reversing land degradation. **Box 1** indicates key messages from the State of the World's Forests report.

This publication frequently uses the phrase "forests and trees." A "forest" is defined as land spanning more than 0.5 ha with trees higher than 5 m and a canopy cover of more than 10%, or trees able to reach these thresholds in situ; it does not include land that is predominantly under agricultural or urban use (FAO, 2015). Although trees outside forests are not technically considered as "forests," according to this standard definition they provide multiple economic, social and environmental benefits (UN, 2008) and so have been included within the scope of SOFO 2018.

Using trees along with forests and referring to planted forests on occasions, SOFO 2018 has consciously left out the term plantations thereby avoiding the controversy of re-defining a forest as distinct from plantations and hiding plantations behind trees.

Table 1 Ten Sustainable Development Goals (SDGs).

Sustainable Development Goals (SDGs)	Related to
SDG 2	Ending poverty in all its forms everywhere
SDG 5	Achieving gender equality and empower all women and girls
SDG 6	Ensuring availability and sustainable management of water and sanitation for all
SDG 7	Ensuring access to affordable, reliable, sustainable and modern energy for all
SDG 8	Promoting sustained, inclusive and sustainable economic growth, full and productive employment and decent work for all
SDG 11	Making cities and human settlements inclusive, safe, resilient and sustainable
SDG 11	Ensuring sustainable consumption and production patterns
SDG 13	Take urgent action to combat climate change and its impacts
SDG 15	Protect, restore and promote sustainable use of terrestrial ecosystems, sustainably manage forests
SDG 15	Combat desertification, and halt and reverse land degradation and halt biodiversity loss

Box 1 Key messages from the State of the World's Forests Report

- a. Governments need to foster an all-inclusive approach that promotes the benefits of forests and trees, engaging all stakeholders.
- b. Strategies to achieve the SDGs should consider interlinkages with forests and trees.
- c. Actions on forests, agriculture, food, land use, rural and national development must be integrated in the future if the 2030 Agenda is to be realized.
- d. Investing in the agents of change will spur entrepreneurship and the sustainable management of forests.
- e. Integrating landscape approaches into national strategies and development priorities is part of building the forests of the future.
- f. Policies must be geared toward incentivizing companies and small producers to engage in sustainable forest management, addressing potential barriers to investment and removing motives for clearing forests.
- g. Corporate responsibility for zero deforestation is key.
- h. Trees, parks and forests are a must for planners designing the sustainable cities and peri-urban landscapes of the future.
- i. Clearer picture of the social, economic and environmental impacts of forests and trees across the SDGs will be critical in calculating incentives and managing sector trade-offs, fashioning forest and food security.
- j. Initiatives, measuring out social safety nets, investing in technology and innovation, and determining the level of support needed for different sectors of the economy.

Pathways to Sustainable Development

SOFO 2018 markets the benefits of forests and trees to policy-makers, the donors and the private sector by advocating integration of forests with the broader sustainable development agenda. The report indicates that it “seeks to examine evidence about the contribution that forests and trees – and the people who use and manage them – can make to sustainable development.” “The objective is to strengthen forest pathways to sustainable development as part of the transformational change needed to implement the 2030 Agenda” (p. 2).

In short, “Pathways to sustainable development summarizes key policy implications, highlighting the need to: raise awareness and market the benefits of forests and trees to policy-makers and beyond; engage the private sector; integrate forests with the broader sustainable development agenda; invest in transforming the informal sector to unlock missed development opportunities and improve employment conditions; undertake national and subnational analytical studies; and improve data availability” (p. xiii).

The existence of quantifiable information is the criterion influencing the choice of targets. SDG indicators are used for most of the targets under SDG15, while for the other nine selected SDGs (whose formulation does not refer to forests) “thematic metrics were developed to show evidence of a relationship between forests and trees and the selected SDG target.”

Considering the relationship between forests and trees to nine SDGs, the respective targets can only be achieved if priority and emphasis are given on achieving SDG 15, especially SDG 15.2 which refers to “By 2020, promote the implementation of sustainable management of all types of forests, halt deforestation, restore degraded forests and substantially increase afforestation and reforestation globally.”

In this context when the report states that “the impacts of forests and trees go well beyond SDG15 to contribute to achieving multiple goals and targets across the 2030 Agenda,” (p. xvi) it is not clear where the priority and the emphasis lie since SDG 15 is at the core to stop immediate deforestation. Without achieving SDG 15 by 2020 none of the other SDGs can be achieved.

In Chapter 2 of the report, while quantifying the contributions of forests to the sustainable development goals, “SDG indicators were used for most of the targets under SDG15, while for the other nine selected SDGs (whose formulation does not refer to forests) thematic metrics were developed to show evidence of a relationship between forests and trees and the selected SDG target” (p. 8).

SOFO 2018 admits that “Quantification of forest contributions to the SDGs involves methodological challenges due to a lack of agreed definitions as well as disaggregated statistics and data sets. In several cases, the methodology for this analysis had to rely on literature, case studies, and assumptions, which can provide an overview of trends in contributions but not exact figures” (p. 65).

Assumptions and Trade Offs

While quantifying contributions of forests and trees to SDGs, the report has constantly used presence of markets and access to markets as significant indicators. So, “landscapes made up of farmland and trees or near the forest edges – ecosystems that can support much larger populations than dense forests” contribute more to poverty eradication and “an association between high forest cover and high poverty rates has been confirmed.” Commenting on relationship between poverty levels and remoteness, SOFO 2018 assumes that “governance and rights in remote areas can also be weak” (p. 10).

This is a clear indication of FAO disincentivizing conservation and protection of natural and primary and intact forests.

Similarly confusing and controversial is how FAO, in this report, deals with the complex issue of extraction and harvesting of wood failing to have a robust analysis of impacts for traditional use and practices, and industrial use for energy and consumption. The tenor of its argument is set on a wrong premise where the report states:

"Modernizing the traditional wood energy sector has the power to improve livelihoods, create sustainable value chains and unlock resources for investments in sustainable forest management. The potential of forests is perhaps no better illustrated than by the fact that wood grows back" (p. xi).

The following inferences from the report explain well the problematic:

- Clear and secure forest tenure rights are key for sustainable woodfuel production, as they foster management practices that ensure regrowth or regeneration at least equal to the level of extraction.
- Woodfuel production and harvesting can lead to sustainable green energy. The widespread availability of woodfuel and its ubiquitous market are opportunities for employment and sustainable development.
- Forests and trees contribute to achieving SDG7 by providing woodfuel for cooking, heating and industrial needs (including power generation and cogeneration of heat and power).
- One widespread practice for improving the fuel properties of wood is to convert it into charcoal (which has a greater energy content by weight than fuelwood) so that it burns more slowly and releases less smoke during combustion.
- Woodfuel is also a major component of the global renewable energy supply.
- FAO has estimated that energy from woodfuel is equivalent to roughly 40% of the world's renewable energy supply, which is as much as solar, hydroelectric, and wind power combined. This figure provides an indication of the major contribution that wood-fuel from sustainable sources can make to the global renewable energy mix.

In SOFO 2018, FAO uses available data and statistical analyses to point out a series of trade offs between forest conservation, production forestry and consumption of forest products to attain sustainable development and SDGs. Eradicating poverty, employment and livelihood generation and food security are being shown as reasons for these trade-offs. FAO also proposes unlocking agricultural economy by linking small holder agriculture in forest areas to global value chain. "Harnessing value chains and taking advantage of private sector capacity can increase productivity and local incomes."

The report further uses data for area under long term management plans to show that such area increased by 2.1 billion ha by 2010, equally distributed between production and conservation purposes. Supporting sustainable logging, and independently verified forest management certification schemes, SOFO 2018 indicates that "certified forest area increased from 285 million hectares to 440 million hectares between 2010 and 2014."

These suggested trade-offs and resulting contradictions emerge from the simplistic notion that "Renewability, resource efficiency and responsible sourcing of forest products are at the heart of the concept of sustainable production and consumption" (p. 45).

Though the report identifies agriculture as one of the causes for deforestation, the strategy involves dovetailing forestry with agriculture with focus on agriculture in the periphery and linked to forests. The dovetailing of forestry and agriculture, where small scale agriculture is advocated to be intensified will have its impact on forestry in terms of transforming subsistence agriculture into catering for the market and cash economy, scaling up and using external inputs for increased production and invasion of alien varieties of seeds which can be damaging for the forest lands in terms of biodiversity and soil fertility loss changing the face of forest based agriculture.

Eliminating emissions from land-use change is critical to achieving the Paris Agreement's goal of limiting warming to 1.5 °C. We are barely 11 years away from a critical juncture (2030) by when we need to act to limit global warming to 1.5°. The SDGs also indicate a time limit of 2030 mostly while it is 2020 for forests and natural ecosystems. At the same time, addressing food sovereignty while minimizing ecological losses is one of the major challenges the world faces, and key to many of the Sustainable Development Goals (SDGs). These aims do not represent choices or trade-offs, but challenges that must be approached in an integrated and holistic manner that respects human rights and ensures ecosystem integrity (Dooley et al., 2018).

The sustainable pathway lies in avoiding conversion of natural sinks and enhancing and protecting terrestrial ecosystems, prioritizing transformative agricultural practices to help eliminate over-production and consumption, including shifting diets and reducing demand for land for agricultural expansion. Where natural forests cannot be further logged, advocating even responsible production and consumption in the forest sector cannot be a policy direction to stem global warming and limiting temperatures to 1.5 or 2° and aiming for sustainable development. The first call is to stop deforestation followed by reforestation and restoration.

Agents of Change: Rights of Local Communities and Smallholders

FAO report advocates policies that secure tenure rights for the poor and vulnerable, including indigenous people, landless farmers, rural women and youth, will go a long way to ending poverty and food insecurity. "Investing in these agents of change will spur entrepreneurship and the sustainable management of forests." SOFO 2018 elaborates on the above when it states:

"Integrating forests into sustainable development strategies requires effective partnerships and private sector engagement. Clear legal frameworks, community engagement and coherent policy measures that balance stakeholder interests are part of the enabling environment needed. Policies must be geared toward incentivizing companies and small producers to engage in sustainable forest management, addressing potential barriers to investment and removing motives for clearing forests" (p. xvii).

According to the FAO report, clear and secure tenure rights are recognized as an important prerequisite for the sustainable management of natural resources. The tenure rights cover at a minimum the right to access, make management decisions and withdraw resources from a particular area.

Ensuring only these sets of rights and avoiding rights over forest land, community rights over forest resources, ownership rights over NTFPs and most importantly, the right to community governance (and not simply community-based management) leading to decentralized forest governance, will not be transformative in action. What is also missing is a clear acknowledgement of the role of indigenous peoples and local communities and FPIC. Most of the time, the report has used terms like small scale holders and stakeholders. Not even right holders.

FAO reports from official country statistics show that in 2010, 3% of global forest area was under community ownership (FAO, 2015). The Rights and Resources Initiative (RRI), found that in 2013 in 52 countries (representing nearly 90% of the global forest area) over 15% of forests—or 512 million ha—were either under community ownership or designated for community control. In addition, substantial areas of forest are *traditionally* managed without legal recognition by local communities and indigenous peoples, especially in Africa and elsewhere where customary land rights prevail (RRI, 2015). Estimating that around 100 million ha of forest are partially under community control, SOFO 2018 concludes that “the proportion of forests under community and smallholder management may be as high as 28 percent of the world’s forest area” (p. 12).

In the context of global efforts to protect the world’s remaining forests, securing collective tenure rights represents one of the most cost effective, sustainable and equitable strategies to protect and restore vital ecosystem functions, conserve biodiversity, and reduce rates of forest loss and degradation caused by agribusiness and other industrial land uses (Dooley et al., 2018).

Whereas FAO, through its SOFO 2018, literally uses the policy of secured tenure rights to open up forests to private sector, investment companies, facilitating forestry enterprises, as source of bioenergy and logging, and linking forests and small holder agriculture to global value chains thus advocating increased commercialization and commodification of forests for sustainable development.

It seems that this overt support to security of tenure and rights for forest communities and small-scale holders where secured tenurial rights define the relationship between the land and forests, and the individual or communities, rather than the state controlled and appropriated forest land, is therefore, geared to attract investors.

To attract both public and private investments, with emphasis on more private sector involvement, the report is filled up with lots of data, information and analysis to open up forests as an attractive destination for investment having multiple values and with synergy across multiple sectors.

Ode to sustainable wood

Across the world, the forest sector has provided numerous examples of sustainable wood production and consumption. These include developing policies that encourage the use of wood products for construction, which has been found to have lower embodied energy than comparable building systems using concrete, steel, or bricks. Wood could be used much more in the construction not only of houses but also other structures (such as bridges), although this could be hampered by regulations that do not specifically cover wood, as well as by certain insurance conditions. Although there are positive signs in some countries, the use of wood in construction is still not increasing on a global scale (p. 45).

Norwegian biorefinery Borregaard produces a wide range of biochemicals, biomaterial and biofuel from wood residues that can substitute oil-based products. Speciality cellulose is consumed by the construction, pharmaceutical and food industries, and is used in the production of cosmetics, filters, hygiene products, textiles and paints. One of its key components, lignin, is used in the production of concrete, textile dyes and food ingredients. Its binding properties allow for a significant reduction in the water and cement content of concrete, thus decreasing energy and water use as well as CO₂ emissions in the production process. Borregaard is the world’s largest manufacturer of second-generation bioethanol, with a production of around 20 million litres per year. At present, the refinery delivers bioethanol from its Sarpsborg facility for heavy goods vehicles and buses in the Oslo region (p. 46).

Using wood (including wood waste and residues) more efficiently to meet this demand – doing “more with less” – is crucial to achieving a more resource-efficient, circular and bio-based economy (p. 47).

Conclusions

It is not surprising and unexpected, therefore, that SOFO 2018 dovetails the sustainable forest management with SDGs in trying to establish “forests and trees” as pathways to sustainable development.

Therefore, one of the key findings of the report indicates that forests are being managed more sustainably, and that forests and trees contribute to achieving SDGs related to: livelihoods and food security for many rural poor; access to affordable energy; sustainable consumption and production; climate change mitigation; sustainable forest management.

From the point of view of achieving SDGs, poverty eradication, food security, sustainable forestry, with the slogan of “forest beyond forestry,” the report basically points to the need for integration of forests to the capitalist economy through sustainable (read certification and such other schemes) supply and value chains in exploiting timber, NTFPs and other ecosystem services like tourism.

Wood as fuel and that it provides more than half of national energy supplies in 29 countries including sub-Saharan Africa, is then extrapolated as “Access to affordable energy,” further adding that “forests supply about 40 percent of global renewable energy in the form of woodfuel – as much as solar, hydroelectric and wind power combined” (p. 88).

Forests are, therefore, seen as the source for next generation renewables through utilization of wood as fuel and ushering in of bio-economy. In that sense, even after the phasing out of the extractive industry, forests will be the next source of extraction as “it is a renewable resource,” which is a flawed argument as natural forests cannot be regained; unless in the garb of increasing forest cover and carbon sequestration there is an increase of trees (read plantations).

In Chapter 4 of SOFO 2018, the key findings seem to pose more challenges than suggesting concrete policies to move forward. From providing informal sector jobs, to agroforestry, tourism, sustainable cities, empowerment of women, climate change adaptation to tackling land degradation and biodiversity loss, sustainable forest management (without any clear definition or conceptual clarity) is conclusively demonstrated as a clear winner. A one stop solution to all, being sold as a win-win situation.

In the process of marketing the benefits of forests and its “true value,” FAO loses the plot when it says, “there is a need for the forest sector to become less forest-centric and to focus more on using the 2030 Agenda as an opportunity for a fresh look at what sustainable forest management means in practice” (p. 92). That practice, as advocated in SOFO 2018, essentially highlights certification schemes, sustainable logging, afforestation and REDD+, increasing biomass stock, sustainable tourism, green infrastructure and green economy, harnessing value chain and taking advantage of private sector capacities, zero-deforestation supply chains, multi-stakeholder partnerships to invest in forests and responsible governance.

This linkage of forests and forest communities to the global capitalist market economy will render the forest communities as mere producers and not owners/stewards of forest resources who protect and conserve forest and biodiversity. Customary rights and laws which protects the rights and property rights of the communities are intrinsically linked to resources and traditional practices and not to the market while tenurial rights define the relationship with land and resource use in terms of market where both the market and investment can clearly identify the relationship and, therefore, is seen as an unlocking potential. The customary rights and laws do not clearly identify that and therefore, in the context of the market, locks up the land and resources. The emphasis on tenurial rights and local governance is a ploy to mitigate potential conflict with a notion of protecting the producers, otherwise the production and profits will both collapse.

Abstract

The Tongass National Forest in southeast Alaska is one of the last relatively intact temperate rainforests in the world. Due to public controversy over old-growth logging, the USDA Forest Service finalized a plan in 2016 to transition out of old-growth logging but not until 2032 as the agency claims it needs to log ~17,000 ha of old growth as “bridge timber” until some 114,000 ha of young growth regenerating from prior clearcut logging is readily available. Transitioning out of old growth logging faster than proposed by the Forest Service would maintain fish, wildlife, and climate benefits along with timber industry needs more aligned with the limits of what the Tongass rainforest can sustain. Recent young growth (mainly 55-year old precommercially thinned stands) inventories on the Tongass suggest that the Forest Service can begin a transition out of old-growth logging within 5 years and on a much smaller (~50,000 ha) and predominately young growth land base than the agency proposes in its transition plan, if certain conditions are met.

“The Tongass National Forest is a national treasure. Today, I am outlining a series of actions by USDA and the Forest Service that will protect the old-growth forests of the Tongass while preserving forest jobs in southeast Alaska. I am asking the Forest Service to immediately begin planning for the transition to harvesting second growth timber while reducing old-growth harvesting over time.”

July 3, 2013 Press Release, USDA Secretary Tom Vilsack

Tongass as a World Class Temperate Rainforest

At 6.8 million hectares, the Tongass National Forest in southeast Alaska is the largest national forest in the United States and one of the world’s last relatively intact temperate rainforests (DellaSala, 2011). This national forest is hemmed in by glaciated Coast Mountains to the east and numerous near-shore islands to the west ranging from the Yakutat Forelands in the north to Prince of Wales Island south (one of the largest islands in North America) (Fig. 1).

Some 90% (>2 million ha) of forests on the Tongass is considered “productive” old growth, consisting of structurally complex, multilayered forests with trees >150 years (Schoen and Orians, 2013, also see Fig. 1). Old-growth Sitka spruce (*Picea sitchensis*) and western hemlock (*Tsuga heterophylla*) forests on the Tongass are global carbon sinks (Leighty et al., 2006) that store atmospheric carbon for centuries primarily because the maritime climate limits fire occurrence. The region’s relatively intact watersheds provide ideal conditions (compared to the lower 48 states) for five species of salmonids (*Oncorhynchus* spp.), a principal food source for grizzly bears (*Ursus arctos*), wolves (*Canis lupus ligoni*, unique subspecies), and bald eagles (*Haliaeetus leucocephalus*).

In spite of its global significance, the Tongass is the only national forest in the nation that still clearcuts (clear-fells) old growth on an industrial scale. Old-growth logging began in earnest in the 1950s with peak logging levels achieved in the 1960s–80s (Fig. 2). At the time, “high-grading” of the largest trees was a common practice that concentrated logging in low-elevation systems and on productive karst (limestone base) topography (Schoen and Orians, 2013).

The Tongass is now at a critical juncture regarding its status as a global carbon sink and relatively intact rainforest. Compared to the Pacific Northwest, which overcut old growth decades ago resulting in a shutdown of federal lands logging due to litigation over the imperiled Northern Spotted Owl (*Strix occidentalis caurina*), the Tongass currently has no endangered species. Therefore, there is a unique opportunity to transition out of old-growth logging to avoid future controversial listings.

In 2016, the USDA Forest Service finalized an amendment to the Tongass land use plan to transition out of old-growth logging if certain conditions were met. The transition would provide a potential means to end decades of controversy where the choices were limited to either protect some or clearcut much of the old growth (Fig. 3). A transition would present a third option that would eventually rely mostly on limiting logging to young forests regenerating from prior clearcut logging.

Data sources: NACP Aboveground Biomass and Carbon Baseline Data (NBCD 2000), Aboveground forest biomass for Alaska, USDA-FS FIA & RSAC (from Data Basin by the Conservation Biology Institute)

Fig. 1 Tongass National Forest, southeast Alaska. Map provided by J. Leonard, Geos Institute. Dark green shows forests exceptionally high carbon-biomass important in climate regulation and climate refugia (DellaSala, 2011).

Fig. 2 (A) Tongass National Forest old-growth forest logged from 1909 to 2015 and current (2018) age of logged young stands. (B) Timber volume logged from 1908 to 2006 on the Tongass National Forest. Volume calculations (cubic meters) are based on green and rough sawn at 1 full inch containing ~ 2.4 cubic meters of usable material. Actual recovery of lumber is greater than estimated long log scale and therefore a conversion factor of 6.25 was used to express the data in cubic meters. Data for both figures were extracted from available timber harvest records courtesy of A. Brackley, USDA Forest Service, Pacific Northwest Research Station, Sitka, AK, United States.

To achieve its transition, the Forest Service specified that it would need to log another $\sim 17,000$ ha of old growth during the next 16 years (presumably to 2032) before getting to $\sim 114,000$ ha of young growth needed to sustain industry over a 100-year period at a projected volume of 287.5 million cubic meters annually.

Setting a Transition Timeline: Young Growth Volume

Determining when to transition out of old growth centers on how much young growth is available now and into the future and the commercial viability of young trees (i.e., can industry make a profit?). Only the volume necessary to meet a transition timeline is estimated herein. More detailed timber volume estimates and a study of economic value of young growth trees are currently in progress.

Adjusting Cumulative Mean Annual Increment (CMAI)—young growth stands on the Tongass must reach 95% of CMAI, generally the time at which annual growth of trees begins to level off before a regeneration (clearcut) harvest is attempted (~ 80 – 90 years, pers. commun. A. Brackley). However, the Forest Service can relax this requirement if logging is deemed consistent with other plan components of its land management plan, which, in this case, is a transition out of old-growth logging. Shorter rotation ages allow capture of timber volume in younger age stands. We argue that a rotation age of 55-years can be used to achieve transition quickly, as this age class corresponds to the oldest young growth stands currently available on the Tongass (Fig. 2) and the average quartile mean diameter-at-breast-height of 28 cm, which is currently being exported on private lands in the region.

Fig. 3 Three choices on the Tongass rainforest: (A) protect some of the old growth for ecological, cultural, and climate benefits; (B) log most of the accessible old growth and convert it to commercially producing plantations; and (C) transition into previously logged and now regenerated young growth (D. DellaSala). Note on the Tongass, regeneration following clearcut logging is via natural seed source. No planting is necessary.

Ecological and Operability Constraints on Young Growth Logging—Based on Forest Service inventories, the Tongass has over 173,000 ha of young growth of varying ages (mostly < 50 years; Fig. 2); 71% of this is within roaded and development land-use designations and technically within the timber base (USDA Forest Service 2014). Notably, the Forest Service uses the most current and complete data available on young growth, which provided a foundation for a faster transition (<http://databasin.org/maps/d4ee7a0d9662463289b17bf429f6a0ff/active>).

For this estimate, we included young stands (55 years) within 240 m of operable roads that were either precommercially thinned (PCT) or commercially thinned (CT), on slopes < 72% (based on prior Forest Service analysis), and not within ecologically sensitive areas (Table 1). Precommercial thinning on the Tongass is designed to reduce competition among densely packed young trees (speeding up growth rates) and usually occurs 15–30 years after stand initiation. A second entry via commercial thinning typically occurs at ~60 years with extraction of commercial product.

Young Growth Timber Volume Projections—Based on the logging constraints proposed, sufficient young growth timber volume would be readily available on the Tongass to meet transition requirements (~287 million cubic meters annually) beginning as soon as 2020 (Table 2). Obtaining young growth volume from these stands would reduce the timber land base by > 60% of the Forest Service’s transition footprint. In sum, ~50,000 ha of predominately young growth PCT and CT stands within five Ranger Districts closest to milling operations could support a more rapid transition with reduced insert “environmental” conflicts.

Young Growth Economics: The Bottom Line

Determining the market potential of young growth on the Tongass is in early stages but initial results are promising (Fig. 4). For instance, a commercial thinning project (“Dragon Point commercial thin”) in 70-year old young growth offered by the Forest Service yielded 28.1 million cubic meters with an appraised value of \$440,035. All four timber sale bids received by the agency were above appraised value and one was 81% above appraisal (<http://sitkawild.org/2014/06/dargon-point-timber-sale-local-wood-local-benefits/>). The private sector (mainly Sealaska Native Corporation) also exports Sitka spruce round logs from 50 to 70-year-old young growth in the region.

Table 1 Ecological and operability constraints for a 55-year old young growth timber base within five Tongass Ranger Districts (Thorne Bay, Craig, Petersburg, Wrangell, Ketchikan) closet to timber mills

	<i>Importance</i>
<i>Ecological constraint</i>	
Karst topography	Known to be highly productive and likely to become future old growth via restoration (also the terrain tends to be unstable due to physical and chemical weathering of the bedrock geology)
Wilderness, land-use II designations, national monuments, inventoried roadless areas	High ecological values, mostly old growth, mostly off-limits to logging (out of the timber base)
Beach fringe, riparian buffers	Highly productive ecotones for salmon, bears, eagles, and other wildlife and where logging is restricted via forest plan standards and guidelines
Slopes > 72%	Unstable and erosive
Natural disturbances	To allow for development of complex early seral forests and succession to old growth
Not in the suitable harvest base	Already restricted due to environmental concerns
<i>Operability constraint</i>	
5 Ranger districts with prior log sourcing	Hauling distance
Precommercially thinned within 240 m of operable roads (as determined by the Forest Service)	Already productive with road access
Precommercially thinned with at least partial overlap with a 240-m road access buffer	May have access problems given part of the stand lies outside the 240-m buffer
Commercially thinned stands within 240 m of road access	Additional young growth sites for volume estimates

Table 2 Timber volume scenarios within five Tongass ranger districts (Craig, Wrangell, Ketchikan, Thorne Bay, Petersburg) projected over a six-decade period using precommercially thinned (PCT) stands within ~240 m of operable roads. Carryover volumes are based on harvest levels remaining consistent for each of the scenarios with the carryover from prior periods being used to supplement the harvest base such that there are no rolling green outs

<i>Time period</i>	<i>Annual cubic meters × thousand</i>	<i>Annual carryover/deficit cubic meters × thousand</i>	<i>Additive annual carryover/deficit cubic meters × thousand</i>
2015–19	142,512	– 4362

2075–79	524,969	290,594	318,106

^aRe-harvest of 2015–19 units begins.

As an important next step to securing a rapid transition, an economic study is needed to determine lumber grade of 55-year old logs, in consultation with experts from the timber industry and Forest Service. Recently proposed on the Tongass, a wood products study would allow mills to sort young growth by “value-added” lumber and determine market response, securing the best possible information on young growth log and lumber recovery, young growth value-added grade recovery, and market response to young-growth wood products.

Climate Benefits of a Rapid Transition

Tongass rainforests not only store more carbon than any national forest in the United States, but also may function as a critically important climate refuge (i.e., first line of defense) given maritime influences that moderate more extreme climate events anticipated for interior Alaska and temperate regions further south (DellaSala et al., 2017). Relatively intact watersheds also provide refuge for old-growth dependent species (including many that are important to subsistence needs), while buffering salmon from cumulative effects of climate change and more extensive logging in the surroundings (especially on private lands) (Watson et al., 2013).

Notably, prior estimates of carbon flux from logging scenarios on the Tongass indicate that *only a no-logging scenario* maintains carbon stores over time. Carbon also has future economic value in terms of avoided costs from global warming pollution and development of carbon-offset markets. For instance, if carbon were stored long-term in old-growth forests instead of being released to the atmosphere by logging, estimated annual economic value of stored carbon would be comparable to revenue generated from Tongass timber sales should carbon markets mature (Leighty et al., 2006). Importantly, an Interagency Working Group on Social Cost of Carbon estimated that the costs of carbon from global warming effects would be \$27–221 per ton by 2050. Recent evidence suggests the costs may be much higher, including large demographic displacements of human settlements along coastlines (Pizer et al., 2014).

Soon after logging old growth, carbon is emitted to the atmosphere via decomposition of logging slash, fossil-fuel emissions from transport and wood processing (e.g., up to 50% of Tongass logs can be shipped overseas), and decay or combustion (within 40–50 years) of forest products in landfills. Planting or growing young trees or storing carbon in wood products does not make up for emissions released from a logged forest, especially one on short timber rotations (< 100 years compared to old-growth forests that store carbon for centuries). Indeed, after an old forest is clearcut, the young forest remains a net CO₂ emitter for 5–50 years, depending on site productivity (see Harmon et al., 1990; Law and Harmon, 2011) (Fig. 5).

Globally, deforestation (8%–15%) and forest degradation (6%–13%) contribute more greenhouse gas pollution than the world's entire transportation network (Estimates are conservative as they were mainly derived from the tropics where the majority

Fig. 4 (A) Young trees on a log deck awaiting processing. (B) Milled beams processed by local Alaskan mill (D. DellaSala).

Fig. 5 Logging on the Tongass National Forest contributes greenhouse gas emissions while depleting fish and wildlife habitat (D. DellaSala).

of forest losses occur—boreal and temperate losses are not available at this time (Intergovernmental Panel on Climate Change, 2007; Houghton et al., 2012). Recognizing the importance of unlogged forests as carbon sinks, scientists have repeatedly called for protecting carbon stored in primary forests as integral to stabilizing global climate change (Mackey et al., 2014), which is why countries have committed to reducing emissions and protecting forest sinks (COP 21 climate agreements).

Tongass Climate Change Refuge: Uncertainties and Risks

Follow Up Research and Monitoring—reliably estimating carbon flux under different transition scenarios requires comprehensive carbon assessment tools. Without the benefit of such analysis, however, the Forest Service claims that logging old-growth forests “could result in *either a net loss or gain of carbon*” (emphasis added) depending on logging practices used even though clearcut logging (a substantial emissions source) is the method of choice on the Tongass (some young tree retentions and small (<4 ha) clearcuts are proposed in young forests within Old Growth Reserves and Beach buffers by the agency). Follow up work, ideally conducted by the Forest Service, in consultation with carbon scientists, is needed to determine logging emissions; however, in prior simulations (as noted), only a no-logging alternative results in continued long-term carbon storage (Leighty et al., 2006).

Climate Shift Happens—effects of climate change on forest productivity represent significant and costly risks to the Tongass’ global status. As the climate warms, other vegetation types may replace carbon-dense conifer forests on the Tongass that evolved during a cooler climate (DellaSala et al., 2017). For instance, during the Miocene millions of years ago, Alaska was a much warmer place dominated by hardwood forests. As current climate change accelerates, it could lower carbon storage potential of conifer forests as hardwoods gradually replaces conifers and some conifers die off (thereby emitting CO₂ as is currently happening with an extensive die-off of Alaska yellow cedar *Cupressus nootkatensis*; Hennon et al., 2012). However, the maritime climate of the Tongass also might ameliorate some of climate-mediated impacts compared to more extreme changes for interior Alaska and temperate rainforests to the south, but only if old-growth forests are intact (DellaSala et al., 2017) (Fig. 6).

In sum, the Tongass is a global carbon sink; however, this sink may increasingly become an emissions source due to old-growth logging (DellaSala, 2011). Choosing a climate responsible and rapid transition for the Tongass would better safeguard Alaska’s climate, comply with the COP 21 Paris climate change agreements and the global pledge by governments and entities to end global deforestation.

“We share the vision of slowing, halting, and reversing global forest loss while simultaneously enhancing food security for all. Reducing emissions from deforestation and increasing forest restoration will be extremely important in limiting global warming to 2°C.” United Nations Climate Summit New York Declaration on Forests (agreed to by 157 governments, including the United States, indigenous groups, corporations, NGOs, and others).

Fig. 6 Relatively intact forest landscape (potential climate refuge) within Mendenhall Glacier National Park near Juneau, Alaska (A. DellaSala).

Conclusions

The Tongass is one of the last places on Earth where primary forests (unlogged) are still relatively abundant but declining. This critically important rainforest provides Alaskans with unparalleled economic (e.g., recreation and tourism economies greatly exceed logging related jobs and revenue), ecological, and climate benefits (Schoen and Orians, 2013). Using Forest Service inventories, a rapid transition could (1) begin in 2020 as 55-year stands become increasingly available compared to the agency's 2032 transition that relies mostly on old growth logging to get to a transition stage; (2) achieved on a much smaller land base (~50,000 ha of young growth vs. a mix of 114,000 ha of young growth and 17,000 ha of old growth); and (3) result in substantially less carbon emissions along with ecological and cultural benefits sustained over time. Under a rapid transition, logging would occur within areas of relatively low controversy, reducing litigation costs and uncertainty of timber supply to local mills. An economic assessment of young growth is needed to fully assess viability of young trees.

The Tongass is the only national forest still clear cutting old growth on an industrial scale. Other national forests such as the Siuslaw in Oregon are generating young growth timber volume as part of a 1990s-transition due to policy reforms enacted. The time for the Tongass to make a transition is rapidly approaching if the Forest Service will act while there is still significant old growth remaining to conserve and without the controversy of future endangered species listings and ongoing timber wars.

Abstract

The magnitude of gross sources and sinks of carbon from current land management practices suggests that, if deforestation and forest degradation from human activities were stopped, and forests were allowed to recover (e.g., harvested forests and the fallows of shifting cultivation), an estimated 4.4 PgC might be removed from the atmosphere each year for the next century or more. Although the cumulative removal by 2100 would amount to ~360 PgC, this long-term estimate represents a gross removal. The net removal would be considerably less because carbon held presently in wood products and in cultivated and disturbed soils would be emitted to the atmosphere even if further deforestation and harvests were stopped. Accounting for these committed emissions, a more likely estimate is that 100–130 PgC might be removed from the atmosphere by 2100 in recovering forests. The quantity is not enough to counter emissions under a business-as-usual future, but it is large (30–60%) relative to the carbon emissions *allowable* for staying under a warming of 2°C. Thus, land management, and forest management in particular, could help stabilize concentrations of CO₂ in the atmosphere and provide a bridge for the transition from fossil fuels to renewable forms of energy.

Introduction

Forests play a large role in the global carbon cycle and thus in the world's climate. Carbon dioxide is the principal greenhouse gas responsible for the warming of the earth, and forests hold nearly as much carbon in their vegetation (about 450 PgC) (1 petagram = 1000 metric tons) and soils (380 PgC) as is contained in the atmosphere (currently about 850 PgC). Furthermore, the carbon held in forests is dynamic. It is released to the atmosphere almost instantaneously when a forest burns, and is withdrawn from the atmosphere and re-accumulated again on land as forests grow. Thus, the potential for forests to change the concentration of carbon dioxide in the atmosphere is large.

The total amount of carbon held in the vegetation of forests at present is about half the amount they would hold in the absence of human activity (Erb et al., 2017), for example, the expansion of agricultural lands and the harvest of wood for fuel and building material. The losses of carbon occurred over centuries as a result of population growth and economic development, and continue today as forests are cleared for new agricultural lands, especially in the tropics. Current net emissions of carbon from land management account for about 10% of total anthropogenic emissions of carbon, which were 11.2 PgC year⁻¹ in 2016.

If society is serious about limiting warming to an increase of no >2°C, emissions of carbon dioxide and other greenhouse gases must be reduced sharply. The *allowable emissions* (the amount of carbon that can be released to the atmosphere with a reasonable chance (66%) of staying below a warming of 2°C) are 160–338 PgC, equivalent to between 14 and 30 years at current emissions rates. Because transitioning from fossil fuels to renewable fuels (largely solar and wind) will not be easy or fast, society will have to find ways to remove carbon dioxide from the atmosphere. Stopping deforestation is not enough. The good news is that terrestrial carbon reservoirs are only half full as a result of past management. Although most agricultural lands are unlikely to be returned to forests, there are large areas of land that could be reforested and large increases in carbon stocks that could be achieved simply through growth of trees within forests.

One approach to removing carbon dioxide from the atmosphere (negative emissions or Carbon Dioxide Removal (CDR)) is through forest growth, increasing both forest area (through reforestation) and carbon storage per unit area (through improved forest management) (Griscom et al., 2017). Other, more high-tech approaches are advanced, but they are largely experimental or being

developed. They suffer from the energy required to remove carbon dioxide from the atmosphere. Trees do it for free, although there is an opportunity cost for dedicating land for forest growth. The other advantage of using forests to remove carbon dioxide from the atmosphere is that the consequences are known and generally benign. The same cannot be said for technological solutions for CDR. Forests provide reservoirs of biodiversity as well as food, fiber, fuel, recreation, and spiritual gratification for millions of people.

Stopping deforestation is not enough. Lands, and forest management in particular, offer the potential to take carbon dioxide out of the atmosphere. How much carbon might be withdrawn from the atmosphere through management, and how rapidly, are the subjects of this article.

The Global Carbon Budget

Before reviewing estimates of the potential for forest management to remove carbon dioxide from the atmosphere, it is useful to explore how forest management has affected carbon storage until now. That background will provide a perspective and some guidance for the future. Annual emissions of carbon to the atmosphere and the distribution of those emissions in the atmosphere, land, and oceans are summarized in the global carbon budget (from [Le Quéré et al., 2018](#)). The units are PgC year⁻¹ averaged over the 10-year period 2007–16.

Emissions		Distribution		
Fossil fuel and cement production	Land management	Accumulation in the atmosphere	Oceanic uptake	Residual terrestrial sink
9.4 ± 0.5	1.3 ± 0.7	4.7 ± 0.1	2.4 ± 0.5	3.6 ± 0.8

An important observation for this article is that the land appears twice in this budget, first as the net emissions from land management (e.g., deforestation and reforestation, harvest of wood products), and second as the net uptake of carbon by land ecosystems (the residual terrestrial sink). As the name implies, this residual terrestrial sink is calculated by difference. It exists because the global carbon budget is balanced, and the four other terms are obtained independently. A terrestrial sink of nearly the same magnitude as the residual is calculated by terrestrial carbon models (DGVMs = Dynamic Global Vegetation Models), strongly suggesting that its causes are reasonably well known. The sink represents the response of terrestrial ecosystems to indirect and natural effects (i.e., CO₂, climate change, nitrogen deposition). More simply, the first terrestrial term refers to the effects of management, and the second to indirect or natural environmental effects on terrestrial ecosystems.

Both terrestrial terms are net values (positive indicates emissions to the atmosphere; negative indicates removals from the atmosphere). The net emissions from land management include the gross emissions from burning and the decay of wood products and cultivated soils, and the gross removals from the re-growth of forests following harvest and the re-accumulation of carbon in soils following agricultural abandonment. Similarly, the residual terrestrial sink is composed of both gross emissions, for example from droughts, forest fires and thawing permafrost, and larger gross sinks from CO₂ fertilization, longer growing seasons, and warming of cold regions.

Separating the management effects from environmental effects is nearly impossible for any unit of land smaller than the globe. Thus, while managed and unmanaged lands can be distinguished, and the emissions from managed lands can be assigned to particular areas, the same is not true for the residual net sink. The residual term applies to both managed and unmanaged lands because they both respond to changes in the environment. As a consequence, assigning the residual sink to particular locations or types of land use is difficult.

Emissions of Carbon From Land Management: The Past

Land management is also referred to as Land Use and Land-Cover Change (LULCC), where land use (LU) includes management within an ecosystem (e.g., wood harvest) and where land-cover change (LCC) includes the conversion of one type of ecosystem to another (e.g., deforestation for croplands). A recent study by [Houghton and Nassikas \(2017\)](#) reconstructed annual changes in five types of LULCC over the period 1850 to 2015: croplands, pastures, tree plantations, industrial wood harvest, and fuelwood harvest. Rates of wood harvest and agricultural expansion were obtained primarily from the FAO after 1960 and from other sources of data before that date. A carbon-tracking (bookkeeping) model was used to simulate conversions and harvests of 20 types of native ecosystems based on the distribution of managed lands relative to native ecosystems. Carbon densities of forests (MgC/ha) in 1700 were adjusted to yield ending (2015) national densities reported by [FAO \(2015\)](#), the assumption being that 300+ years of land and forest management changed the average carbon density of a country's forests. Carbon densities decreased as primary forests were converted to secondary forests as a consequence of wood harvest. The turnover times of wood products depended on end uses, which included fuelwood (1 year⁻¹), pulp and paper products (0.1 year⁻¹), and lumber products (0.01 year⁻¹) ([FAOSTAT, 2015](#)).

[Houghton and Nassikas \(2017\)](#) used a bookkeeping model with prescribed changes in the carbon density of vegetation and soils in response to management. The model accounted for all pools of carbon on managed lands, including living vegetation, dead vegetation (or slash), wood products, and soil carbon. The emissions of carbon from anthropogenic burning and draining of peatlands in Southeast Asia were included. Rates of decay and regrowth varied geographically but were assumed constant from 1700

to 2015. That is, the effects of elevated CO_2 , climate change, and nitrogen deposition on rates of carbon accumulation or loss were not included in the calculations. Only the direct effects of land management were considered. Thus the analysis quantified the first terrestrial term in the global carbon budget.

The calculated annual emissions of carbon from land management in the tropics and northern and southern mid-latitudes are shown in Fig. 1. Annual net emissions, globally, varied for most of the last 165 years between 0.5 and 1.0 PgC year^{-1} , grew to a peak of about 2.0 PgC year^{-1} in the 1990s, and declined since then. Although the net emissions from northern temperate zone and boreal forests dominated global emissions until about 1910, those lands have become a growing net sink for carbon since about 1960. Currently that net sink is about $-0.3 \text{ PgC year}^{-1}$ (Table 1). In contrast, the emissions from tropical forest management generally increased over the last 165 years to a current value of 1.4 PgC year^{-1} .

Total carbon emissions from land management amounted to 145 PgC over the period 1850 to 2015 (Table 2). By far the greatest emissions resulted from the expansion of croplands, in part because cultivation results in a loss of 25–30% of the carbon in the top meter of soil, whereas other types of management have lesser effects on soils. Estimated emissions from the expansion of pastures were probably underestimated by Houghton and Nassikas (2017) because the study did not include the losses of soil carbon from overgrazing. Note that carbon accumulated in forests (negative emissions) as a result of fire management in the U.S. and as a result of the expansion of tree plantations, globally.

The analysis by Houghton and Nassikas (2017) provides a starting point for asking how past management might be changed to maximize the removal of carbon dioxide from the atmosphere. More specifically, how much carbon might be removed from the atmosphere if deforestation and wood harvest were stopped, and if shifting cultivation were to be replaced by permanent agriculture, allowing fallow lands to return to forests?

Potential Negative Emissions

The critical information for estimating the potential for forests to remove carbon dioxide (negative emissions) is the *gross* rate at which carbon is removed from the atmosphere as a result of land management. So far this article has discussed net emissions of carbon. It is now appropriate to discuss the gross emissions and removals that comprise net emissions. Gross emissions result from burning and decay of wood and from oxidation of soil organic carbon, and the gross removals result from forest growth (following harvest) and recovery of soil carbon when cultivated lands are abandoned.

Not all land management practices yield gross emissions. For example, there are no sinks with deforestation; gross emissions are the same as net emissions. In contrast, the harvest of wood includes both positive emissions from decay of debris and oxidation of wood products and negative emissions in recovering forests. Rotational uses of land generally have large gross emissions, often removals offsetting emissions, with lower net emissions than uni-directional land conversions (e.g., deforestation).

Forest Biomes in Temperate and Boreal Zones

Most countries in the temperate zone and boreal regions carry out systematic and repeated forest inventories that provide estimates of forest growth, harvest, and mortality. With some exceptions, forest dynamics and, more broadly, land use and management are generally better documented in these countries than they are in tropical regions.

According to the analysis by Houghton and Nassikas (2017) annual net emissions of carbon from the world's temperate and boreal forests were ~0.5 PgC year^{–1} for most of the 19th century but declined after ~1940 and became negative after ~1970 (Fig. 1). Gross removals of carbon from the atmosphere (negative emissions) were twice as large, averaging a little more than –1.1 PgC year^{–1} in recent years (Table 1), and provide one estimate of the role that non-tropical lands could play in slowing global warming if the (positive) emissions from deforestation and forest degradation were eliminated.

The term “degradation” is perhaps unfortunate here. It refers to a reduction in carbon storage: a harvested forest holds less carbon in its trees than it did before harvest (Kurz et al., 2018). Unfortunately, even sustainably managed forests are “degraded” in terms of carbon stocks, although they are far from degraded in a forester's view.

Not all emissions will be eliminated if harvests are stopped. Some of this year's emissions result from pools of wood products and debris that have built up over decades and from continued losses of soil carbon associated with recent changes in management or land use that have not yet come to equilibrium. The legacy or committed emissions will continue even if the clearing and harvesting of forests are discontinued, as illustrated in Fig. 2A, in which all land use and harvests were stopped after 2015. Gross (positive) emissions did not fall to zero in 2016 when land harvests were stopped but did decline exponentially, as expected from rates of decay, and were about 0.1 PgC year^{–1} by 2100.

Gross negative emissions will also decrease if deforestation and harvests are stopped because young forests will no longer be created, and aging forests remove carbon from the atmosphere at a lower rate. The net effect of stopping any further management results in an initial surge in negative emissions but then a decline as gross removals fall faster than gross emissions. Over the period 2016 to 2100, 19 PgC would be removed from the atmosphere if deforestation and degradation were discontinued in the temperate zone and boreal regions (Table 3); i.e., if no wood harvest were to occur after 2015.

Stopping all further LULCC after 2015 sets a biophysical upper bound on negative emissions without consideration of land ownership, costs, or other social factors. To provide alternatives to such an extreme change in management, Houghton and Nassikas (2018) considered two additional simulations. In one, they stopped only deforestation after 2015 but allowed wood harvest to continue into the future at today's rates. In the second simulation, they enhanced the carbon sequestration potential of harvested wood products by increasing their lifetimes by a factor of 10 and by harvesting more efficiently (halving the amount of slash or woody debris left on the harvested site). Again, these simulations represent what is possible, biophysically; they are not projections of future land management.

Fig. 2 Annual net and gross emissions of carbon from land management in northern mid-latitudes (A) and tropical forests (B). After 2015, clearing and harvesting of forests was stopped in the simulations and lands in shifting cultivation (forest fallows) were allowed to return to forests. From Houghton, R.A. and Nassikas, A.A. (2018). Negative emissions from stopping deforestation and forest degradation, globally. *Global Change Biology* **24**, 350–359.

Table 3 Cumulative amount of carbon (PgC) added to (+) or removed from (–) the atmosphere between 2016 and 2100 according to simulations described in the text

Simulation	Temperate and boreal regions	Tropical regions	Global
Business-as-usual (includes shifting cultivation in the tropics)	–10	56	46
Stop all LULCC after 2015	–19	–15	–34
Stop all LULCC after 2015 and abandon shifting cultivation	–19	–98	–117
Stop deforestation only	–8	–2	–10
Extend lifetimes of wood products	–28	–8	–36

From Houghton, R.A. and Nassikas, A.A. (2018). Negative emissions from stopping deforestation and forest degradation, globally. *Global Change Biology* **24**, 350–359.

Increasing harvest efficiency and lengthening the lifetimes of wood products increased cumulative negative emissions in temperate and boreal forests to –28 PgC (Table 3). This simulation resulted in the largest cumulative negative emissions for temperate and boreal zones.

Surprisingly, the negative emissions from stopping deforestation (–8) were less than in the business-as-usual simulation (–10), where rates of deforestation and harvest continued at 2015 rates. The explanation for lower negative emissions is partly that wood harvest resulted in a net gain of carbon in wood products and forests, and partly that some deforestation was for tree plantations. When deforestation was stopped, more harvests were in primary forests (higher biomass) instead of plantations, and the associated emissions were higher.

In general, both negative and positive emissions declined in the simulations. Negative emissions declined because the area of secondary forests declined; and that area declined because harvesting was stopped. Once recovered from harvest, forests were assumed not to accumulate additional carbon in the bookkeeping model. Positive emissions declined as well, in part because of reduced deforestation and reduced harvests, but in part because the large pools of wood products present in 2015 also declined. Future net emissions can be thought of as the balance between starting (2015) pools of wood products (future sources), on the one hand, and starting areas of secondary forests (future sinks), on the other. Rates of release and uptake by these respective pools are not necessarily symmetric, and annual net emissions will vary over time. Fig. 2A shows the two declining gross emissions (positive and negative) after 2015, when all LULCC was discontinued.

Tropical Forest Biomes

In the tropics the *gross* rate at which carbon is removed from the atmosphere as a result of land management is uncertain. Because systematic forest inventories are rare, the area of tropical forests growing as a result of current and past land use is not known. At one extreme, it is possible that most tropical forests are recovering from previous harvests, clearing, and abandonment (i.e., they are

dynamic). At the other extreme, it is possible that most forests in the tropics are fully grown (i.e., static). Management is so rare in the latter case, that most forests are “recovered” and not “recovering”—or at least not accumulating carbon as a result of management. Large areas of secondary forests suggest large gross sinks (negative emissions), that could become *net* sinks if the activities generating positive emissions (harvests and degradation) were stopped.

A Conservative Estimate

One estimate of gross removals (negative emissions) in the tropics was given by Houghton and Nassikas (2017) ($-0.5 \text{ PgC year}^{-1}$ over the decade 2006–2015). That estimate is conservative because the only rotational land use the analysis included was harvest of wood, while a major form of rotational land use in the tropics is shifting cultivation. Although data on the practice of shifting cultivation are lacking at a tropics-wide scale (the study by van Vliet et al. (2012) is an exception), there are at least two indications that shifting cultivation, or something very much like it, has increased the area of secondary, or growing, forests.

The term shifting cultivation is used broadly here to include any rotational land use. It includes the traditional practice: clearing forest, cropping the land for a few years, allowing forest recovery during a period of fallow (5–20 years), and then re-clearing. But it also includes any form of temporary slash and burn agriculture that clears land every few years. The practice refers to the temporary use of forest for short-term crops or pasture, subsistence agriculture, agroforestry, illegal logging, and other uses. It represents the area of forest that was recently or is repeatedly used.

An Excess Loss of Forest Area

One indication that rotational land use in the tropics is more common than assumed by Houghton and Nassikas (2017) is the observation that rates of tropical deforestation reported by the FAO often exceed the increase in permanent agricultural lands (croplands and pastures) (Fig. 3). The most recent Forest Resource Assessment (FRA) (FAO, 2015) reports changes in forest area only since 1990, but as much as 40% of deforestation since then has been for “other land”. Other lands are defined by FAOSTAT (FAOSTAT, 2015) as all lands that are not permanent croplands, pastures, or forests: the area is simply calculated as a residual. The reported changes raise two questions. If forests were not converted to croplands or pastures, what were they converted to? And, what were the rates of deforestation for these other lands before 1990, when the data were first reported?

Since 1990, the annual conversion of tropical forest to other land has averaged about 3 million ha/year and was sometimes as high as 6 million ha/year. The annual increase seems too large to be accounted for by increases in urban or settled lands or by an expansion of mining or other non-agricultural activities. It also seems unlikely that all of the “excess loss” is an error. Some forest loss may have been overestimated by the FAO (precision varies among countries reporting), and the sum of the reported increases in croplands and pastures may have been underestimated, but the discrepancy is too large to be entirely the result of error.

The rates of tropical deforestation reported by the FAO (2015) (an average of 9.0 million ha/year between 2000 and 2012) are not larger than the rate of forest loss observed with satellites (Hansen et al., 2013) (average of 9.4 million ha/year).

Fig. 3 Annual rates of tropical forest loss and annual rates of gain in crops and pastures and forest plantations for those tropical countries losing forests. Only in the years around 2005 and after 2012 was the loss of forest area “explained” by increases in plantations and agricultural areas. For all other years, the loss of forest area (shaded) exceeded the increase in agricultural area. From Houghton, R.A. and Nassikas, A.A. (2018). Negative emissions from stopping deforestation and forest degradation, globally. *Global Change Biology* **24**, 350–359.

Because the FAO defines deforestation as the loss of forest to other cover types, while Hansen et al. (2013) include temporary losses of forest area from logging and burning, one might expect the FAO estimates of deforestation to be lower than the rates of forest loss reported by Hansen et al. (2013). And that turns out to be the case when gross rates of forest loss are adjusted for bias (Tyukavina et al., 2015). The adjustment yields an average gross forest loss of 11.7 million ha/year for the period 2000–2012. Thus, rates of deforestation as reported by the FAO (9.0 million ha/year) appear not to be overestimated when compared with independent estimates.

Differences in methods and definitions may explain other discrepancies in reported rates of forest loss. For example, the FAO (2015) reports declining rates of deforestation, while some satellite data suggest an increasing rate (Hansen et al., 2013; Kim et al., 2014). The FAO defines deforestation as the conversion of forest to another land cover (FAO, UNFCCC), while the measurements of forest loss by satellite include disturbances (e.g., storms, droughts, or fires) and harvests, neither of which are considered deforestation by the FAO. If satellite data could identify the fate of deforested lands, the two estimates of deforestation might converge and reveal an unambiguous trend.

It is possible, of course, that anthropogenic rates of deforestation are declining in the tropics, while non-anthropogenic disturbances are increasing. In that circumstance satellite and ground inventory data would be different but not necessarily inconsistent. For example, recent drought-induced fires in the Amazon have increased the emissions from fires at the same time that emissions from deforestation have declined (Aragão et al., 2018).

According to analyses of Landsat data (De Sy et al., 2015; Tyukavina et al., 2015), shifting cultivation does not seem to account for a large fraction of deforestation, but pixel by pixel analyses of Landsat data (spatial resolution 30 m) do not necessarily detect changes within the mosaics of land covers that include shifting cultivation (Molinario et al., 2015). Similarly, selective logging may be undetected if it does not reduce forest cover to <25%, the cut-off used by Hansen et al. (2013). Quantification of forest degradation with satellite data may be possible with LiDAR data (Baccini et al., 2017).

Area of Primary Forest

A second indication that tropical forests are lost at a higher rate than inferred from changes in agricultural area comes from FAO estimates of the percent of forests considered primary, or unmanaged. FAO (2015) reports that only 36% of tropical forests were primary forests in 2015. In contrast, the reconstructions of LULCC by Houghton and Nassikas (2017) yielded percentages that were 81% primary. Those reconstructions overestimated the area of primary forests because they used *net* annual changes in agricultural area to drive deforestation, when, in reality, gross rates of forest clearing may be higher than net losses, and balanced by rates of agricultural abandonment (i.e., reforestation). That is, some amount of forest clearing may be simultaneous with agricultural abandonment, and net changes in area probably underestimate the rate of secondary forest formation.

A potentially more important explanation, however, is that land-use statistics from FAOSTAT fail to account for shifting cultivation. The agricultural division of FAO does not count shifting cultivation as agricultural land, but the forestry division does count the conversion of forest to shifting cultivation as deforestation.

The repeated use of forests is important because rotational land uses, such as shifting cultivation and wood harvest, lead to large gross losses and gains of carbon. Disturbances result in carbon emissions, while subsequent recovery, even partial recovery, results in carbon sinks (negative emissions). If the areas are large, the gross sources and sinks of carbon are also large, although the net flux may be nearly zero if the same lands are used repeatedly. On the other hand, if the temporary use of land is a minor activity, most tropical forests may be considered grown. One would expect rates of carbon accumulation in mature forests to be lower than in growing forests. The observation that grown forests may be sinks for carbon (Phillips et al., 1998; Luyssaert et al., 2008) suggests that those sinks may be attributable to environmental changes (e.g., CO₂ fertilization) rather than to recovery.

Some have argued that the small proportion of primary forests reported by the FAO is a result, not of recent management, but from the use of tropical forests long ago. There is a growing recognition that disturbances, both natural and anthropogenic, have long-lasting effects on forest composition, structure and dynamics (Vlam et al., 2016). Thus, many of the “old-growth” forests in the Amazon may still be recovering from ancient (pre-European) human impacts. This possibility seems unlikely because forests cannot accumulate carbon at high rates for a long time (500 years) without having biomass densities much higher than observed.

A Simulation With Shifting Cultivation

In a more recent analysis, Houghton and Nassikas (2018) assumed that the discrepancy between forest loss and agricultural gain represented an expansion of shifting cultivation. They constructed a simulation in which the “excess loss” of forests (Fig. 3) was interpreted as the conversion of forests to shifting cultivation, swidden, or some other temporary use of the land. Furthermore, once lands were in this temporary category, they were repeatedly cleared, used, abandoned, and then used again in the model. The first time a forest was cleared for this temporary use, the conversion was called “deforestation.” Thereafter, the clearing of fallow was within the shifting cultivation cycle; re-clearing did not include conversion or deforestation.

In the conservative estimate Houghton and Nassikas (2017) assumed the “excess forest loss” replaced worn out croplands, which, in turn, were re-classified as “other lands.” That is, forests were cleared for new croplands, while old croplands were abandoned. Forests were lost, but cropland area was unchanged. That assumption resulted in 81% of forest area being primary forest, not the percentage estimated by the FRA (FAO, 2015) (36%). To account for a larger area of secondary forest in their more recent analysis, Houghton and Nassikas (2018) started the analysis (in 1700) with 33% of tropical forest area already in temporary

use. These areas in use continued to be used through the simulations, changing only in response to reported increases in “other lands.” “In use” means that young forests (fallow) were repeatedly used, never recovering to primary, or grown, forests. Under this assumption, the fraction of forest area in primary forests at the end of the simulation (2015) was similar to the FAO’s estimate of 36%. The assumption is simplistic, but historical inaccuracies in the area of shifting cultivation will have little effect on the net and gross fluxes between 1990 and 2015, the period important for predicting current gross removals and future negative emissions.

Over the 10-year period 2006–2015, gross negative emissions in the tropics averaged $-0.5 \text{ PgC year}^{-1}$ under the (conservative) simulation from Houghton and Nassikas (2017) and $-3.3 \text{ PgC year}^{-1}$ under the (generous) simulation from Houghton and Nassikas (2018).

The generous simulation was used to calculate the gross negative emissions that would result if rotational land uses were stopped in 2016. Gross emissions fell immediately, and the gross negative emissions became net emissions because forest growth continued even after deforestation was stopped. These gross negative emissions were large in this simulation (Fig. 2B) because the fallow forests in shifting cultivation were allowed to recover. The simulation assumed that shifting cultivation would be replaced by permanent agriculture, enabling fallow lands to return to forest. Stopping harvest of wood in the conservative simulation resulted in negative emissions of 15 PgC between 2016 and 2100 (Table 3). Including the abandonment of shifting cultivation (83 PgC) led to cumulative negative emissions of 98 PgC by 2100.

The decline in tropical negative emissions that accompanies what amounts to a moratorium on deforestation and the abandonment of rotational forest use seems steep, but it is consistent with rates of growth of tropical forests ($2.6 \text{ MgC ha}^{-1} \text{ year}^{-1}$ in the analysis versus $3.05 \text{ MgC ha}^{-1} \text{ year}^{-1}$ for secondary tropical forests in Latin America (Poorter et al., 2016)). With this rate of growth, forests reach 75% of their initial carbon density in about 50 years and were assumed to recover to their initial biomass density in another 50 years. Lower rates of growth would extend the period of negative emissions but would also lower the amount removed per year. Thus, the total removal over the long term (~ 100 years) is little changed by assuming different rates of growth.

Harvesting more efficiently and lengthening the lifetimes of wood products had a modest effect on projected tropical emissions (-8 PgC) (Table 3) because harvests of industrial wood (as opposed to fuelwood) are low in the tropics. Stopping only deforestation generated cumulative negative emissions (-2 PgC), much smaller than those created by abandonment of shifting cultivation (-83 PgC).

Global Synthesis

The greatest potential for negative emissions in the tropics results from stopping deforestation and allowing the fallows of shifting cultivation to return to forests. Outside the tropics the greatest potential comes from lengthening the lifetime of wood products. Adding together the results from the simulations with the highest negative emissions yields a maximum of 126 PgC ($98 + 28$) (Table 3). The potential is somewhat less than the total loss of carbon from changes in LULCC since 1850 (145 PgC) (Houghton and Nassikas, 2017), but a full recovery is unlikely as much of that loss resulted from the expansion of permanent agricultural lands, which are unlikely to be reforested. In fact, new agricultural lands needed for a growing world population will probably reduce the potential further unless increased production is accomplished through increased yields rather than expanded areas.

Putting the tropical, temperate, and boreal forests together, yields a global gross sink (2006–2015) of $4.4 \text{ PgC year}^{-1}$. Although this sink is large (47% of global emissions from fossil fuels for the same decade), it will be offset to some extent by emissions from wood products and slash and from changes in soil carbon that were initiated before 2016. Accounting for these delayed emissions, the net sink for carbon will be greatest immediately after harvests cease and will decline as regrowing forests age. The net global carbon sink obtainable if deforestation and harvests were stopped would be -34 PgC by 2100 ($15 + 19$). If, in addition, lands in rotational agriculture were allowed to return to forest, the cumulative sink would be -117 PgC (Table 3). Extending the lifetimes of wood products would add another 9 PgC ($28 - 19$) for a global maximum of 126 PgC.

The management options considered here suggest potential negative emissions as large as $4.4 \text{ PgC year}^{-1}$ if the gross annual emissions of $5.5 \text{ PgC year}^{-1}$ from deforestation and degradation were stopped. On the other hand, the gross negative emissions of $4.4 \text{ PgC year}^{-1}$ are largely offset by the emissions that are likely to continue even without further deforestation and harvests. Emissions will continue from native soils recently brought into cultivation and from the pools of carbon in wood products accumulated over past decades. One can manage emissions by stopping deforestation or harvest; it is more difficult to eliminate emissions from existing paper products, landfills, wooden buildings and infrastructure. The *net* negative emissions of 117 PgC by 2100 would amount to only 31% ($117 \text{ PgC} / (4.4 \text{ PgC/year} \times 85 \text{ year})$) of the amount that would be sequestered if the gross sinks in 2016 were to continue to 2100 (i.e., without counting the committed emissions).

Three Broad Categories of Forest Management for Reducing Emissions or Increasing Sinks

One can imagine three types of carbon management using land. First, stopping tropical deforestation would reduce current emissions by $1.3 \text{ PgC year}^{-1}$ (including the emissions from draining and burning of peatland soils in Southeast Asia) (Houghton and Nassikas, 2017). To the extent the residual terrestrial sink is in forests, stopping deforestation has the additional benefit of reducing the loss of this sink.

Second, stopping degradation, in this case the harvest of wood, may not be the most effective strategy for managing carbon. On the one hand, a gross source of $1.0 \text{ PgC year}^{-1}$ could be avoided if harvests were stopped globally and previously harvested forests were allowed to recover. On the other hand, the harvest of wood for long-lasting products could result in a greater storage of carbon on land (the sum of carbon in forests and in harvested products) if the harvests were sustainable. The analysis by Houghton and Nassikas (2017) found, however, as others have for Europe, that industrial wood harvests led to a *reduction* in carbon storage in countries outside the tropics, 18% less than in a simulation without industrial wood harvest. The reduction in forest biomass (30.9 PgC) was larger than the increased storage in products and slash (14.6 PgC). Harvests did not result in greater carbon storage because harvested forests were sometimes cleared for agriculture, thus eliminating the sinks that would otherwise have been attributed to harvest. The net effect varied through time and among regions. As shown in one simulation, increasing the lifetimes of wood products resulted in a larger effect, increasing cumulative negative emissions to -28 and -8 PgC in the extra-tropics and tropics, respectively (Table 3).

Strictly speaking, stopping deforestation does not lead to negative emissions. Neither does stopping wood harvest, although sustainable harvests could result in an accumulation of carbon in long-lasting wood products. Nevertheless, reducing emissions of carbon is equivalent to increasing sinks, in this case allowing existing gross sinks to be manifest as net sinks.

The third type of carbon management, and one that does increase negative missions, is the expansion of forest area. In these analyses forest expansion was simulated by allowing the lands in shifting cultivation to return to forests (for a sink of 83 PgC by 2100) (Table 3). No other lands were assumed to be available for forest expansion, and in this respect, the estimate is conservative. However, the expansion of forests in boreal and temperate zone regions, though good for taking carbon out of the atmosphere (biogeochemistry), may have a net warming effect because of changes in biophysics (albedo, evapotranspiration, turbulence), depending on the emissions of volatile organics and resulting aerosols (Spracklen et al., 2008).

Net Versus Gross Fluxes

This discussion has focused on the gross sources and sinks of carbon resulting from deforestation and wood harvest. From the perspective of managing carbon, gross emissions and gross removals are the more appropriate metric because these fluxes identify the potential for reducing emissions or enhancing sinks. In contrast, *net* emissions from land use is a poor indicator of potential. Net emissions today are about 10% of total anthropogenic carbon emissions, implying that land management is likely to have only marginal effects on reducing emissions. On the contrary, when rotational land uses in the tropics are considered, the gross emissions ($5.5 \text{ PgC year}^{-1}$, globally) (Table 1) represent 37% of total carbon emissions (fossil fuel emissions are currently about 10 PgC year^{-1}). From the perspective of carbon management, gross emissions are the fluxes with management potential.

In addition to the losses and gains of carbon on land as a result of management, there is also a large net uptake of carbon ($3.6 \text{ PgC year}^{-1}$) thought to be caused by environmental changes (e.g., elevated CO_2 , nitrogen deposition, or changes in climate). That residual terrestrial sink is consistent with the accumulation of carbon in forests, both managed and unmanaged, as measured by forest inventories (Pan et al., 2011). Together with the gross sources and sinks from forest management, these two pathways demonstrate the importance of land, and particularly forests, in the global carbon budget (Fig. 4). When gross emissions are considered, land management accounts for 37% of total emissions (not 10%), and land, including both management and the residual sink, accounts for 43% of the global sink (not 30%). Represented this way, terrestrial ecosystems and land management appear large in the global carbon balance. The challenge is to preserve and enhance negative emissions while eliminating or limiting their associated positive emissions.

Conclusions

Two conclusions emerge from this investigation. First, without a massive, global program of forest expansion, the potential for negative emissions from ending deforestation and degradation is modest (on the order of 100 PgC). Even under the unrealistic projections simulated here, the potential for land management to withdraw carbon from the atmosphere is small relative to the potential for fossil fuel use to add carbon. But this is the wrong comparison. The appropriate comparison is between potential for negative emissions and the total carbon emissions *allowable* for staying within a warming of 2°C ($160\text{--}338 \text{ PgC}$ from 2015 onwards (Rogelj et al., 2016)). In that comparison, the potential for negative emissions from forest management represents 30–60% of the allowable emissions. This finding is fundamental. Land management is vital if 2°C , or less, is indeed the goal.

Because the estimate of 100 PgC is based on biophysical potential, and not on economic or ownership conditions, it is likely *generous*. On the other hand, there are at least three reasons why it is *conservative*. First, it assumes that existing supplies of wood products, as well as pools of slash and soil carbon, will all be lost to the atmosphere. It is possible that some of these pools could be managed in such a way as to “seal” them from oxidation (i.e., keep them from the atmosphere). Second, stopping harvest of wood, thereby allowing forests to grow to maturity (or over maturity), misses the opportunity to remove carbon from the atmosphere through sustainable harvests of long-lasting wood products, where the total carbon in products plus forests is potentially greater than it would have been in unharvested forests. Sustainable forestry with a goal of long-term storage would increase the potential of negative emissions. And third, the analysis does not consider the full possibility for expanding forest area. There may be large areas

Fig. 4 Average annual sources and sinks of carbon for the period 2006–2015. (Left) Net emissions from land use. (Right) Gross emissions from land use. From Houghton, R.A. and Nassikas, A.A. (2018). Negative emissions from stopping deforestation and forest degradation, globally. *Global Change Biology* **24**, 350–359.

of degraded or unused lands that could be reforested if carbon removal were profitable. Such reforestation would have to be done carefully, taking into account other values besides carbon, such as biodiversity and human rights.

The second conclusion is that negative emissions are possible because ecosystems are below their natural carbon densities as a result of land use. That is, potential negative emissions are directly coupled to past positive emissions. There is nothing magic about these negative emissions. They simply restore carbon lost previously. The corollaries of this conclusion are (1) that negative emissions will diminish as forests recover to their undisturbed state (negative emissions will only work for a few decades) and (2) that much of that recovery will have occurred before 2100, according to these simulations.

The residual terrestrial sink, on the other hand, the accumulation of terrestrial carbon believed to be caused by changes in the global environment, is entirely different (see “The Global Carbon Budget” section). This terrestrial sink is not the result of land management. If the processes responsible for that residual sink (e.g., CO₂ fertilization, climate change) continue, the sink may also continue. However, one of the reasons for keeping the warming to <2°C is that these natural sinks may be reduced as a consequence of warming. Ecosystem respiration, for example, is temperature dependent. Furthermore, thawing of permafrost and forest die-back from droughts seem to be increasing, potentially lowering the current and future sink. Satellites have recorded the greening of the planet (increased productivity) for decades, but a recent analysis reports an increase in browning (reduced productivity) (Pan et al., 2018). The observations are worrisome for the persistence of the residual terrestrial sink, and without it, management of the global carbon budget will be much more difficult.

Old-growth, or primary, forests have an important role in storing carbon. First, per hectare they hold more carbon in their vegetation and soils than secondary forests, and their deforestation would result in large positive emissions of carbon. It is not clear how much of the residual carbon sink, currently 3.2 PgC year⁻¹, is in old-growth forests. The world’s forests account for much of this sink (Pan et al., 2011), and there is evidence that old-growth forests continue to accumulate carbon in biomass and soil for centuries. From the perspective of negative emissions, it seems prudent to maintain existing areas of old-growth forest as well as to allow large areas of secondary forests to age/grow.

Abstract

Roadless areas are free from any kind of road(-like) infrastructure and their direct or indirect impacts on the ecosystems. The largest tracts of ecologically most valuable roadless areas refer to large unfragmented forests regions, both in the tropics and the boreal zone (Amazon, Congo basin, East and Southeast Asia). Among all terrestrial ecosystems, roadless forests are the single most important strongholds of regulating ecosystem services: among others, soil protection, water retention, buffering of the local and regional climate and mitigation of global climate change via capturing of atmospheric carbon. But roadless areas also comprise much demanded natural resource assets, such as timber, often also minerals and space for agricultural development. There is a substantial conflict between diverse short-term economic interests and the long-term conservation of roadless areas. Large roadless areas can serve as a measurable surrogate for the most pristine and functional ecosystems. Roadlessness is a property of areas, which are not impacted by roads; it can be used as a proxy for assessing ecosystem integrity and the absence of many anthropogenic disturbances. We recommend that policy-makers give roadless areas conservation priority over areas that have already been fragmented. It is essential to establish roadlessness as a criterion for the planning of ecosystem-based, cost-effective sustainable development. In parallel with measures to protect roadlessness, we recommend alternative approaches to mobility that can work under roadless conditions, e.g., related to railroads, blimps and other low-energy technologies with low infrastructure requirements. Even if “climate-friendly” renewable energy was available for road transport on a large scale, the construction, existence and operation of roads would continue to severely impair ecosystem functionality.

How Do Roads Impact Ecosystems?

The manifold impacts of roads on ecosystems start with local and direct effects caused by construction, continue when the road is used and maintained, and then radiate into the wider landscape (Font et al., 2014; Forman and Alexander, 1998; Riley, 1984). Environmental degradation, changes in ecological processes, and decline of biodiversity on all hierarchical levels are the consequence (Chaplin-Kramer et al., 2015; Fahrig and Rytwinski, 2009; Forman, 2000; Forman et al., 2003; Kleinschroth and Healey, 2017; Martin et al., 2000; Riitters and Wickham, 2003; Young, 1994) (Figs. 1 and 2).

Direct impacts of road construction include the physical conversion of sites, soil compaction, dust, salt, and heavy metal pollution, changes to the microclimate by creating extended surfaces that heat up and do not retain water as well as the creation of edges that are vulnerable to windthrow of trees. Noise and light pollution degrade the quality of faunal habitats, and vehicle collisions cause increased wildlife mortality (Benítez-López et al., 2010; Ferreras et al., 2001; Gibbs and Shriver, 2005; Jaarsma et al., 2007; Kaphegyi et al., 2013; van Langevelde et al., 2009; Seiler, 2001; Wadey et al., 2018). Furthermore, roads cause the fragmentation of continuous ecosystems and the isolation of remnant landscape patches, create barriers, cutting off populations and restricting gene flow, which can eventually lead to local extinction (Ceia-Hasse et al., 2017; Epps et al., 2005; Rytwinski and Fahrig, 2015). The barrier effect of roads is species-specific and depends on body size, mobility and speed of fauna. In addition to the road itself, fragmentation of populations of certain species can become much more severe by building fences along roads to prevent wildlife crossings and accidents (Epps et al., 2005; Linnell et al., 2016). Roads reduce landscape connectivity, alter species behavior, and can lead to changes in species composition (Forman et al., 2003; Hansen and Cleverger, 2005; Freudenberger et al., 2012).

Fig. 1 Schematic representation of different categories of road impacts on biodiversity. Road impacts diminish with the distance from the road. From Ibisch, P. L., Hoffmann, M. T., Kreft, S., et al. (2016). A global map of roadless areas and their conservation status. *Science* **354**(6318), 1423-1427, supplementary material.

The “contagious effect” of roads (Selva et al., 2015) describes how newly constructed roads in previously inaccessible areas trigger a cascade of disturbances and impairments of ecosystems. Indirect impacts of roads are caused by promoting socioeconomic activities such as resource extraction, agriculture or tourism, which previously were rather restricted or even absent. They provide access to remote and scarcely inhabited areas and often lead to deforestation, urbanization, mining, human-caused wildfires, hunting, poaching, and fishing, all together resulting in further degradation of habitats and ecosystem functionality (Laurance, 2009; Laurance and Arrea, 2017; Liu et al., 2008; Selva et al., 2011; Trombulak and Frissell, 2000). Especially in forest ecosystems the microclimatic and biotic changes along the road edges can increase the risk of wildfires and trigger further destabilizing consequences for ecosystem functionality (e.g., Chaplin-Kramer et al., 2015; Lembrechts et al., 2017; Foley et al., 2003; Norris et al., 2012; Eigenbrod et al., 2015).

Direct impacts of roads can be quantified in various ways by counting wildlife road kills or measuring habitat loss and fragmentation, whereas indirect impacts can be very complex, time-lagged and go far beyond main roads that often trigger the development of smaller trails and paths, which makes it more difficult to understand and assess them (Forman et al., 2002; Freitas

Fig. 2 Impressions of diverse road impacts on forests. Logging roads and trails often start the cascade of degradation. Among the most prominent impacts are soil compaction and opening up forest canopies (A: Skidding trail in temperate Carpathian beech forest, Ukraine; B: Harvester providing access to planned clearcut area in boreal forest, Arkhangelsk region, Russian Federation). In mountain areas downstream road impacts multiply first direct effects; they commonly lead to erosion, destabilization of slopes and disturbance of rivers (C: Recently improved road in Andean montane rain forest, Ecuador). Roads provide access to highly vulnerable areas such as peatlands, drive land use change and cause changes in the landscape hydrology (D: Oil palm plantation on peatlands replacing a former tropical peat swamp forest at the edge of the Klias reserve in Sabah, Borneo, Malaysia). Roads become veins of colonization in remote regions introducing contagious effects into the wider landscape (E: Main road with a belt of increasing settling and land use activities such as cattle ranching in northern Kalahari, Kavango region, Namibia). Roads are often built even in the centre of protected areas leading to loss of habitat, change of microclimate and increasing the risk of wildfires or neobiota (F: Road with tourists within Ku-Ring-Gai National Park, Australia). All photographs by Pierre Ibisch.

et al., 2015; Jędrzejewski et al., 2018; Selva et al., 2011; Shilling et al., 2015; Wilkie et al., 2000). Direct and indirect effects of roads on ecosystems are scale-dependent and have to be analyzed with regard to their spatial scopes. Forman and Alexander (1998) termed the area influenced by roads “road-effect zone” (REZ). A REZ comprises the areas which extend beyond an actual road but are still affected by road construction, usage or maintenance. Type and degree of impact changes, depending on the zone that is affected. The REZ is determined by various factors such as the distance from the road surface, environmental conditions, season, landscape structure, topography, or traffic intensity (Forman and Deblinger, 2000).

Species and ecosystems react specifically to the diverse combinations of road effects and landscape conditions; impacts can be asymmetrical along roads and vary temporally or seasonally (Ibisch and Selva, 2017; Kleinschroth et al., 2016; Morán-López et al., 2017). Hence, it is not possible to identify a single road-effect zone combining all direct and indirect road effects on biodiversity and

species. For instance, a highly altered and structurally impoverished grassland impacted by a new concrete road with heavy traffic cannot be compared to a complex, intact and functional forest ecosystem crisscrossed by narrow dirt roads used by poachers and illegal loggers. In mountains, there are also downstream effects of roads that can extend over large distances. These would be related to run-off, soil erosion, and river water quality, among others (Ibisch and Selva, 2017; Seutloali and Beckedahl, 2015). In the Southwest Amazon rainforest region, indirect effects have been recorded up to 45 km around main roads (Southworth et al., 2011). In contrast, the road-effect zone for desert turtles in California is over 400 m from the road (Boarman and Sazaki, 2006). Bat activity increases more than threefold between 0 and 1600 m from the road (Altringham and Kerth, 2016). For anurans in Canada, Eigenbrod et al. (2009) estimated a REZ of 250–1000 m. Dutch birds were affected by roads within a distance of 40–2800 m from the road, depending on the species and traffic volume (Reijnen et al., 1995). A population decline extends over distances up to 5 km for mammal species and up to 1 km for bird species (Benítez-López et al., 2010). Most of the direct negative impacts caused by roads are at a distance of one kilometer to the nearest road (Ibisch et al., 2016).

Roads and Roadless Areas in Forests

Often, forests are mapped as roadless within heavily roaded landscapes such as in Germany. However, upon closer inspection these areas are by no means truly road-free ecosystems; rather, there are countless forest trails and forest roads that have not yet been mapped (Hoffmann and Ibisch, 2017). Even if these are not public roads and characterized by very low traffic intensity, they can contribute to ecosystem vulnerability:

- As forests are the most biomass-rich and structurally most complex terrestrial ecosystems, they are especially vulnerable to physical, chemical and biological degradation mechanisms that can be referred to the presence of roads. The complex, three-dimensional structure established by trees—often organized in various strata—together with high biomass facilitate a pronounced physical moderation and regulation of environmental conditions. For instance, forests produce their own cooler, more buffered and moister microclimate, which is a key property to their resistance and resilience against disturbance (e.g., Norris et al., 2012). By opening up the canopy and creating linear breaches, roads affect the self-regulating capacity of forest ecosystems, reducing the microclimatic buffering capacity.
- The combination of higher temperatures and lower humidity along roads, the presence of combustible fuel such as remnants of cut or dying trees, often amplified by secondary vegetation with combustible plants, and the presence of people, who tend to inconsiderately light fires, multiplies the risk of forest fires.

What Are Roadless Areas and Where Are They?

Roadless areas are free from any kind of road(-like) infrastructure and their direct or indirect impacts on the ecosystems. In the research for the first global map of roadless areas (Ibisch et al., 2016), a 1 km buffer was chosen as a relatively conservative measure, acknowledging that there are impacts that can be recorded beyond this distance from the road. Due to the absence of the road impacts described above, roadless areas play a special role in the conservation of biodiversity and ecosystem functionality (Martin et al., 2000; Stritholt and DellaSala, 2001; Crist et al., 2005; Selva et al., 2011). They increase landscape connectivity between habitat patches and protected areas (Stritholt and DellaSala, 2001; Goetz et al., 2009) and can contribute to the conservation of native, vulnerable, and endangered species (Campaign, 2001; Gelbard and Harrison, 2003). They are particularly essential for species that require and move across large territories (Crooks, 2002; Blake et al., 2008; Kaphegyi et al., 2013; Kuemmerle et al., 2018). Roadless functioning ecosystems have a higher buffer capacity and are more resilient than roaded areas, making them less vulnerable to the effects of climate change (McGarigal et al., 2001; Crist et al., 2005). Even small roadless areas can be of importance, as they serve as habitat, stepping-stones, and climate refugia for certain species, as well as reference areas for restoration. Clearly, biological diversity is positively related to the size of a conservation area (Develice and Martin, 2001), and larger roadless areas are especially valuable.

The very first OpenStreetMap (OSM)-based global analysis of roadless areas distribution across Earth's biomes showed substantial geographical differences (Ibisch et al., 2016). The Tundra and Rock and ice-covered biomes were nearly roadless. A high share of roadless areas was also found in Tropical and Subtropical Grasslands, Savannas, Shrublands, and Moist Broadleaf Forests in Montane Grasslands and Shrublands, Deserts and Xeric Shrublands, as well as in Boreal Forests/Taiga. Half of the Mediterranean Forests, Woodlands, and Scrublands appeared to be roadless, whilst in Temperate Broadleaf and Mixed Forests the roadless share was <50%. In the Tropical Forests large roadless areas exist in South America, Africa, and Southeast Asia. The largest tracts of roadless areas exist in the Sahara, but also in forest regions such as the northern and western Amazon and the boreal forests in northern and northeastern Russia and Canada (Figs. 3 and 4).

Highest road density can be observed in the Temperate Broadleaf and Mixed forests biome, especially in industrialized countries with high population density and economic outputs, such as the (eastern and central) USA, most European countries, South Korea or Japan. This reflects both the completeness of the road data sets and actual economic development. In Asia, South America and Africa road infrastructure is rapidly developing. In Africa and Southeast Asia, in many countries, the national share of (1 km OSM) roadless areas between 2013 and 2018 has substantially decreased by >30% (e.g., Sri Lanka from 66% to 26%; own unpublished

Fig. 3 Roadless area in eastern Noel Kempff Mercado National Park in Bolivia. Vast tracts of tropical moist forests in contact to Cerrado woodlands and savannas represent huge complexes of free-willed, functional ecosystems Photograph: Pierre Ibisch.

Fig. 4 Map of global roadless area patch sizes in km². From Ibisch, P. L., Hoffmann, M. T., Kreft, S., et al. (2016). A global map of roadless areas and their conservation status. *Science* **354**(6318), 1423-1427.

data). This would mainly be due to intensified OSM mapping efforts, but should also reflect progressing road infrastructure (see below, following section).

To understand the relative importance and ecological value of roadless areas it is important to assess their ecologically relevant features and the presence of non-road related threats. An example for roadless, but used landscapes are rangelands. Often large, intensively managed agricultural areas, mining or military sites appear as roadless areas if the distance to the road is >1 km. Still, they are not necessarily free from traffic, and land use can have severe degradation effects on ecosystems (Hoffmann and Ibisch, 2017). As in the context of assessing the quality of wilderness areas, certain criteria can be applied for further understanding the relative ecological value and conservation priority of roadless areas. In the context of the first global map, Ibisch et al. (2016) proposed the Ecological Value Index of Roadless Areas (EVIRA). This index encompasses three indicators. The first indicator consists of the Ecological Functionality Index (EFI) (Freudenberger et al., 2012), the second is patch size and the third is connectivity of the patches using Thiessen polygons. Ecological Functionality was weighted by 50% the last two by 25% each. The largest tracts of ecologically most valuable roadless areas refer to large unfragmented forests regions, both in the tropics and the boreal zone (Amazon, Congo basin, East and Southeast Asia; Fig. 5). There are also very important roadless areas in some temperate and subtropical regions (e.g., Himalaya, eastern Russia, Caucasus, eastern Mediterranean).

What Are the Data Needs and Prospects Regarding Roadless Big Data Management and Research?

Cartographically, roadless areas are identified as areas that remain once roads and buffers (on each side of the road) are removed from the country data set. The buffer can be adapted to the road category or condition of the ecosystem (e.g., 1 or 5 km, see Ibisch et al., 2016). For the first global map of roadless areas open-source data was used, created by OpenStreetMap (OSM). OpenStreetMap works with volunteered geographic information (VGI), where citizens collect confirmable geodata (Goodchild, 2009; Mooney and Corcoran, 2013). The 1 km buffer was applied on each side of all roads across all road categories that are included in the OSM road data set (Ibisch et al., 2016) (Fig. 4).

The road network from 2013 was used in the roadless area study. It showed gaps in some regions, especially in Southeast Asia (Ibisch et al., 2016; Hoffmann and Ibisch, 2017). Because OSM is a crowd-sourcing project, data collection is an ongoing process (Mocnik et al., 2017). The OSM dataset of 2013 comprised almost 37 million km of roads. By 2018, the worldwide OSM data on roads has doubled. The OSM data set is updated constantly, missing roads but also newly constructed roads are added. Several quality assessments were conducted to evaluate the quality of OSM data (Koukoletsos et al., 2011; Barron et al., 2014; Zhao et al., 2015). In a study published in 2017, the authors found that OSM is 83% complete in >40 countries (Barrington-Leigh and Millard-Ball, 2017). The popularity of OSM is increasing and with it the number of mapped roads. Citizens shall be encouraged to actively participate in creating geodata for open access purposes. A new road data set was published by GLOBIO in 2018 with 21 million kilometers of roads that also incorporated OSM road data for the European Union (Meijer et al., 2018). An automated road mapping algorithm that would use artificial intelligence identifying different road types on satellite images would be highly useful for a reliable global monitoring (Laurance, 2018).

One of the downsides of global data sets is the size of the data and the consequent processing time and required computer capacities. Big data has become an issue in many scientific fields. The amount of data is increasing exponentially, but systems that can process this large amount of information are more likely to exist in commercial enterprises than in conservation-oriented research entities. Big data processing is challenging (Demchenko et al., 2012). This is related both to the amount of data and to the existing infrastructure and architecture, which, due to the volume, diversity, speed, truthfulness, volatility and quality of the data, cannot process the information the way it was previously processed (Nasser and Tariq, 2015). Big data with high resolution need storage space and proper running systems to handle and maintain them (Marx, 2013; Bargellini et al., 2013). This field is developing fast, and hopefully, in the future, it will be affordable for a broader public. Although the roads are well mapped in OSM according to their location in most of the regions the meta data or attributes accompanying the data are often insufficient. Information on the road category, lane and or width would be helpful in assessing the impact of roads more precisely. Traffic intensity is not yet included in the OSM data, but can be used together with population density information to assess roadless areas at risk of conversion due to demographic pressure. Even though there is an increasing amount of freely available data, geodata are not always accessible and not consistent enough to be used on a large scale. Download times for large datasets can easily exceed 24 h (unless they are integrated into systems like Google Earth Engine) and companies offering cloud computing services for data processing are initially very expensive.

Roadless Areas and Society

The societal view on roadless areas shifts with changes in socioeconomic lifestyles. Indigenous, forest-dwelling people often recognize disadvantages and risks related to roads such as diseases, poachers or invading settlers (e.g., Finer et al., 2008; Clements

et al., 2018). Abrupt contact with modern life-styles via new roads has been observed to socially disrupt local communities in remote forest regions. Worldwide attention was paid to the case of a road project through the Isiboró-Securé National Park and Indigenous Territory in Bolivia, where indigenous peoples effectively protested against the government's development plans (El Deber, 2018).

In remote rural areas with predominantly agriculture-based livelihoods, local people by tendency would strive for improved road access. Case studies have indicated that roads reduce poverty and increase consumption growth, and the incidence of hunger seems to increase with distance to roads (compare Ibisch et al., 2016, Table S10, supplementary material), but there are also socioeconomic risks (Alamgir et al., 2017). Today, most relevant actors would consider road infrastructure an essential condition for economic development (Fan and Chan-Kang, 2005; Turner, 2006; Calderón and Servén, 2014). Especially in the case of forests, roadless areas comprise much demanded natural resource assets, such as timber, but often also minerals and open space for agricultural development. The substantial conflict between short-term economic interests and the long-term conservation of roadless areas must not be denied.

The general awareness for the impacts of the global road network on ecosystems is relatively underdeveloped. When the first global map of roadless areas was published in 2016 there was a substantial global media echo reflecting that journalists recognized the importance of the topic, several of them acknowledging that the fragmentation of Earth took place largely unnoticed, although virtually everyone uses roads. Theoretically, the current challenges to conventional mobility that led to overcrowded and polluted cities and faces the need to move away from fossil energy sources, could trigger innovation towards more ecosystem-friendly solutions. Unfortunately, the recent hypes around electro-mobility and autonomous smart driving perpetuate visions related to individual automobiles that require roads. Currently, roadless mobility options, including railroads or low-energy flying devices with limited requirements for permanent infrastructure (e.g., zeppelins, blimps), do not seem to be sufficiently developed for representing an attractive alternative.

Roadless Areas Policy: What Are the Messages for Policy Makers?

With the global population expected to reach over 11 billion by 2100 (United Nations, 2017) and the global ecological deficit gradually increasing up to 8380 million global hectares (Gha) (Global Footprint Network, 2018), a bold policy statement of setting aside half of Earth as permanently protected areas for biodiversity conservation has been suggested for humanity to stave off a cataclysmic extinction event (Wilson, 2016). Large roadless areas can serve as a measurable surrogate for the most pristine and functional ecosystems. Given the importance of roadless areas for sustaining essential services to society, and their rapid diminishment globally, the key message to policy-makers is clear: Give roadless areas conservation priority over areas that have already been fragmented. *Roadlessness* is a more or less easily measurable condition of an ecosystem serving as a meaningful proxy for its integrity and the absence of many anthropogenic disturbances. It is essential to establish roadlessness as a criterion for the planning of ecosystem-based, cost-effective sustainable development (Ibisch et al., 2016).

Roadlessness is tightly linked to the concepts of wilderness or intactness. Such global templates focus mainly on forests and include the "High-biodiversity wilderness areas" (developed by Conservation International), "Last of the Wild" (The Wildlife Conservation Society and Center for International Earth Science Information Network, Columbia University) and "Intact Forest Landscapes" (Greenpeace and partners). Another global prioritization scheme was suggested focussing on ecologically functional regions under climate change (EcoSocioClimateWise priority setting model; Freudenberg et al., 2012). Global priorities according to all these templates turn out to focus heavily on roadless forests. To ascertain that development is sustainable on the long-term, it is important to secure regulating and maintaining ecosystem services. Among all terrestrial ecosystems, roadless forests are the single most important stronghold of regulating services: among others, soil protection, water retention, buffering of the local and regional climate and mitigation of global climate change via capturing of atmospheric carbon (Fig. 6). As a possible solution, some have proposed balancing the value of an area for species conservation, as a proxy indicator for maintaining ecosystem services, with its value for food production, as an essential provisioning ecosystem service (Laurance et al., 2014).

The added value and novelty of roadlessness is that it is based on one of the most important direct and indirect key drivers of biodiversity loss. The extent of roadless areas or even simply road density can be easily used as a measurable entity assessing the extent of anthropogenic pressures at multiple scales. The conservation of roadless areas represents a proactive approach, in contrast to reactive approaches that are directed at mitigating or reversing biodiversity losses ex post (see Brooks et al., 2006, for a comparison of proactive and reactive priority-setting in global conservation). A proactive approach favoring policies for ecosystem-based sustainable development bears several advantages. Most importantly, the long-term opportunity costs for protection of roadless areas will often turn out to be lower than the ones resulting from dissection by roads and subsequent exploitation of an area. Proactive policies may also come with a lower political cost. Sparing regions from road development will help forego both immediate protests by informed stakeholders and posterior opposition by people negatively affected by unsustainable development unfolding in the region.

There is an urgent need for a global strategy and relevant legal frame development for the effective conservation, restoration and monitoring of roadless areas and the ecosystems they encompass. The USA initiated this process by protecting over 20 million ha of roadless area >2000 ha each, amounting to approximately 1/3 of its national forest system (see Stritholt and DellaSala, 2001). Starting with the US Wilderness Act (1964), indirectly promoting conservation of roadless areas, the US Forest Service adopted the Roadless Area Conservation Rule (2001) hampering road construction, road reconstruction, and timber harvesting in inventoried

Fig. 6 Tropical moist forest in a protected roadless area with the Maya Biosphere Reserve, Guatemala, providing important regulating ecosystem services such as water retention and mesoclimatic cooling and buffering Photograph: Pierre Ibisch.

roadless areas on National Forest System lands, clearly enhancing species conservation (Loucks et al., 2003), but not without severe political conflicts (Bies, 2006). No such legal frame exists in other more densely populated parts of the world such as Europe, where the importance of roadless areas has only been underlined in some reports on fragmentation (Jaeger et al., 2011), besides scientific calls for roadless areas conservation (Selva et al., 2011; Psaralexi et al., 2017).

As an important first step, policy-makers should commission a fine-scale inventory of roadless areas and their value for sustainable development (see above: Roadless areas and society). In the official national report of Greece towards the European Environmental Agency (Kati, 2018) the number and extent of roadless areas have been introduced for the first time as a fragmentation index and as an indicator for monitoring the fragmentation rate of natural and semi-natural areas (SEBI 13). Such national reports adopt the system of Streamlining European Biodiversity Indicators 2020 (EEA, 2012) under the scope of monitoring the progress of each Member State towards achieving Aichi targets (UNEP/CBD/COP, 2010) and the European Unions' 2020 Biodiversity Strategy targets (EC, 2011).

The most direct proactive measure for roadlessness is a regional moratorium for road construction in roadless areas with an identified high priority. A complementary policy may consist in proactively reducing the future demand for roads. This may be achieved by efforts to promote provisioning ecosystem services elsewhere, e.g., by ecologically intensifying agricultural production in already cultivated and disturbed areas. There is the urgent need to discuss sufficiency in the context of road infrastructure: Although options for further shortening travel routes may exist, certain densities of road infrastructure should be acceptable without the need for ever reducing travel times (Hoffmann and Ibisch, 2017). A maximum threshold of an ecologically tolerable road density should be lower in regions that have yet experienced only moderate disturbance from road development. Additionally, any approach should take into account ecosystem-specific vulnerability.

A moratorium for road construction can be accomplished through establishment of protected areas that are managed according to legal prescriptions that exclude road construction and thus conserve the state of roadlessness. So far, the global system of protected areas has performed poorly in effectively conserving roadless areas, as these are not recognized by governments as *sui generis* (unique) conservation targets (Ibisch et al., 2016). Many roadless areas enjoy *de facto* protection due to natural factors that hamper physical access, such as steep or swampy terrain (Fig. 7). However, with technological progress, enhancing economical resources and increasing pressures from population growth and more or less justified economical interest, this *de facto* protection is precarious. In addition, the economic value of resources harbored in a roadless area may increase. For example, forest in a roadless area may become more attractive to extraction in an otherwise exploited landscape, and with it for road construction. For these reasons, a wise policy will proactively impose a moratorium for road building in key roadless areas, for instance, by establishment of strict protected areas.

Cases may occur where a road construction moratorium is considered impossible, or not opportune under given sociopolitical circumstances. If avoidance is no option, decision-making on roadless areas should explore all options for maximum reduction of road impacts. These options (in order of decreasing preference) include: re-routing a planned road, bundling it together with existing linear infrastructure, and maximizing size of roadless fragments left over from dissection (Laurance et al., 2014).

Fig. 7 Intact Southwest Amazon rain forest in Peru. Large remote roadless areas allow for conserving vast tracts of valuable ecosystems with their functions and services, even without formal protection. But with progressing development they are at risk if protected area policies do not recognize roadlessness as key criterion for nomination and prioritization. Photograph: Pierre Ibisch.

Proactive policies and measures, despite their above described advantages, may still be overturned by road development interests. In these cases, policy-makers should recur to reactive approaches. In the course of compensatory measures that would target minimizing net loss of biodiversity, environmentalists should vehemently insist for an appropriate *quid pro quo*: Any loss of a roadless area through the construction of a new road should at least be compensated with the dismantling of another road that recreates a roadless area of the same ecological value (Hoffmann and Ibisch, 2017). As long as roads are continued to be built, however, the single most important policy is strict regulation of subsequent human activities in the region. First and foremost, areas to the side of a new road must be kept safe from “contagious development,” a cascade of exploitative land use leading to the short-sighted desire for new roads (Ibisch et al., 2016). This then generates new economic interests, thus perpetuating the process until a former roadless area and its functional ecosystems are “used up” (Laurance et al., 2014; Selva et al., 2015).

In parallel with measures to protect roadlessness, work on alternative approaches to roadless mobility needs to be intensified. Even if environmentally friendly renewable energy might turn out to supply road transport on a large scale, roads will continue to severely impair ecosystem functionality. The currently observable megatrends such as electromobility and autonomous driving illustrate the path dependency, which masters the current (and future) mobility discourse.

Conclusions and Outlook

- There is strong evidence for the ecological importance of roadless areas. It is related to the absence of complexly interacting, direct and indirect anthropogenic drivers of ecosystemic stresses.
- Roadlessness, in many ecosystems, is becoming a rare attribute. It is a proxy for ecosystem integrity that can be assessed more or less easily, and shall serve as criterion for conservation and land use planning. Extent and ecological quality of roadless areas (such as Ecological Value Index of Roadless Areas—EVIRA) are recommended for the global reporting on the accomplishment of the Sustainable Development Goals, especially those targeting sustainable infrastructure and the conservation of terrestrial ecosystems.
- First existing models that show the way to develop monitoring systems and policies for conserving roadless areas deserve special attention.
- Published maps and datasets of roadless areas substantially underestimate the extent of roads, but data quality is rapidly improving.
- The enhanced and dynamic mapping and monitoring of both extent and ecological quality of roadless areas is urgently needed for building up a global observation system and informing regional, national, and local policy makers.

- As dozens of millions of road kilometers crisscross the global terrestrial ecosystems and the negative impacts of roads on biodiversity have been extensively studied, there is the need to establish a *roadless ecology* that further proves and quantifies the multiple environmental and socioeconomic benefits of roadlessness.
- A discourse on “road sufficiency” is needed (“How many roads should be enough under given conditions?”). Slight improvements in access and reduction of travel time cannot be justified at the cost of degrading the last ecologically valuable roadless areas.
- The evolution of mobility technologies seems to be trapped in a path-dependency carefully maintained by the stakeholders involved in road-dependent mobility. It is therefore equally important that research highlights the benefits and avoided damage of alternative approaches to mobility and transport, which are likely to include more conventional technologies such as railways or modern, environmentally friendly, low-energy flying vehicles.

Acknowledgments

PLI and MTH co-conceived the first draft of the manuscript and edited the final version. SK and VK contributed to the writing, especially of the section on roadless policy. PLI acknowledges the research professorships “Biodiversity and natural resource management under global change” (2009–15) and “Ecosystem-based sustainable development” (2015 onward) that were awarded by Eberswalde University for Sustainable Development. MTH is supported by a grant from the Institute of Botany of the Polish Academy of Sciences Krakow (fellowship to students of interdisciplinary doctoral studies at the IB PAS).

Abstract

Most monarchs (*Danaus plexippus plexippus*) overwinter in the volcanic mountains of central Mexico clustering in oyamel fir (*Abies religiosa*) forests described as a hot-water bottle, blanket, and umbrella that maintain a microclimate warm enough for the butterflies not to freeze, but cool enough to save lipids for northward migration. In the mid-1990s butterflies covered 21 ha of forest, but by 2017–18 the population had dropped more than 80% and the butterflies covered only 2.5 ha, less than half the minimum population size to be out of the danger of migratory collapse. As monarchs spread throughout North America over multiple summer generations, they lay eggs exclusively on milkweed (*Asclepias* spp.). Monarchs are threatened by milkweed loss, pesticides, logging, and climate change. The monarch is a symbol of conservation and cooperation and people are working across sectors and national boundaries to protect this familiar and beloved butterfly for future generations.

Biodiversity Importance

Social and Cultural Importance of Monarchs

The monarch, *Danaus plexippus plexippus* (Linnaeus, 1758), with its dramatic orange-and-black stained-glass like wings, is one of the most well-known butterflies (Fig. 1).

Monarchs play an important role in science and in the popular imagination. For generations students in North America have reared monarchs in classrooms during lessons on metamorphosis, mimicry and coevolution. As a result, adults and children alike have learned to recognize and revere monarchs as they lay eggs on milkweed and nectar on flowers in gardens and urban parks. This familiarity and knowledge has positioned the monarch as a critical wildlife ambassador and flagship species for conservation.

The monarch is unique among insects in that its iconic status unites people across national boundaries and across the political spectrum who admire the butterfly and its wondrous migration (Gustafsson et al., 2015), a fact visualized in its many uses as symbol of conservation and cooperation. The monarch is an emblem of transnational conservation initiatives and is on the logo of the Commission for Environmental Cooperation of the North American Free Trade Agreement. A monarch icon is used as the verification symbol for nongenetically modified food products. Celebrated for their annual migrations across international borders, monarch images are commonly used as symbols of migration (Fig. 2).

Monarch icons are commonly used to mark buildings offering sanctuary to migrating peoples. In Mexican folklore, monarchs represent the souls of departed love ones and Day of the Dead celebrations coincide with the arrival of the first fall migrants.

Fig. 2 Photograph by Tierra Curry of a monarch butterfly migration mural painted by artist Roger Peet in Minneapolis, Minnesota.

Across sectors of society, passion for monarch butterflies has led to numerous protection efforts, including volunteer habitat creation and monitoring efforts as well as visits to overwintering colonies. In an attempt to quantify this passion, one survey of U.S. households estimated that people would be willing to grow monarch-friendly plants and make donations to monarch conservation organizations up to a value of \$6.6 billion U.S. (Diffendorfer et al., 2014). Other studies have estimated the time spent volunteering to help monarchs at nearly 34,000 h per year valued at \$750,000 U.S. (Ries and Oberhauser, 2015; Semmens et al., 2018). Thousands of people in Mexico volunteer to protect the monarch's winter habitat from illegal logging, and tourism at monarch winter sanctuaries in Mexico generates approximately \$2.8 million U.S. in direct annual income (Semmens et al., 2018). While people are clearly willing to pay to protect this iconic butterfly, the long-term wellbeing of the monarch is invaluable.

Ecological Importance of Monarchs

Monarchs play a valuable role in the web of life because they provide food for a number of species. Monarch caterpillars and eggs provide food for many invertebrate predators including ants, flies, spiders, lacewings, and wasps, and migrating and breeding adults are food for numerous predators including birds, wasps, spiders, mantids, and dragonflies (Oberhauser et al., 2015). Black-backed orioles (*Icterus abeillei*) and black-headed grosbeaks (*Pheucticus melanocephalus*) consume millions of monarchs at their overwintering sites in Mexico (Brower and Calvert, 1985). Small forest mammals such as the black-eared mouse (*Peromyscus melanotis*) also consume large numbers of overwintering monarchs (Glendinning, 1993).

Despite its prominence as a representative of the pollinator community, the monarch's value as a pollinator has not been extensively studied. Monarchs nectar on a wide variety of flowering plants at a continental scale and could serve as incidental pollinators for many species. This contribution may be significant due to the butterfly's abundance and long-distance migrations.

Natural History of Monarchs

Description and life cycle

The monarch butterfly (Lepidoptera: Nymphalidae) is mostly orange and black with a 4-in. wing span. The orange wings have striking black-lined veins and a black margin with two rows of white spots on the black margin; the spots are never on the orange background. They are native to North America but have spread globally and now occur in 91 countries; populations in North, Central, and South America are genetically distinct from other populations (Pierce et al., 2014; Zhan et al., 2014).

Monarchs lay their pearly eggs singularly on milkweed plants (genus *Asclepias* and related genera), which serve as the sole host food for caterpillars. Eggs hatch in 3–8 days and larvae take 9–14 days to pass through five instars, or stages between molts. Larvae emerge as small whitish larvae with black heads and molt into tubular caterpillars with bands of black, white, and yellow and two pairs of protruding black antennae-like filaments (Fig. 3).

Larvae form a green chrysalis with gold dots and pupate into an adult within a few weeks (Fig. 4).

Migration

North American monarchs are renowned for their migration of more than 4000 km, one of the longest of any insect. At the end of summer, most monarchs east of the Rocky Mountains, by far the largest monarch population in the world, fly from the northern United States and southern Canada to the mountains of central Mexico to overwinter in high-elevation coniferous forests. In spring this “super generation” of monarchs flies north again to lay eggs in the southern United States. Successive generations then live for only a few weeks, continuing to fly north and spread throughout the eastern United States and southern Canada. The final summer generation will live for seven or more months and return to the forests of Mexico where their ancestors overwintered (Fig. 5).

A second smaller population migrates from states west of the Rockies to California coastal zone forests to overwinter. While overwintering monarchs form clusters, dense concentrations of adults huddled together on tree limbs and trunks.

Ecology of Forests Used for Overwintering

Eastern migratory population overwintering forests

Early attempts to track monarch migration began in the late 1930s, but not until 1975 did guides Ken Brugger and Cathy Aguado first record the location of overwintering grounds in the Trans-Mexican Volcanic Belt west of Mexico City (Urquhart and Urquhart, 1976; Malcolm, 2018).

The butterflies overwinter on five isolated mountain massifs within an 800 km² area in the states of Michoacán and México where the combination of high altitude (2400–3600 m) and tropical latitude (19–20°N) provides suitable microclimate conditions for monarch overwintering. By migrating south before the winter in the northern hemisphere, monarchs avoid freezing. The cool conditions in the mountains of Mexico prevent them from becoming too active and depleting lipid stores needed to survive the winter and return north the following year. Ambient temperatures that are too warm could cause the butterflies to break reproductive diapause or migrate too soon and nectar sources are sparse during winter months.

Monarchs cluster tightly on tree boughs and trunks (Fig. 6).

The forests where they gather are dominated by oyamel fir (*A. religiosa*) and in the absence of disturbance the canopy closure is > 70% (Navarrette et al., 2011). The dense canopy has been described as an umbrella and a blanket that protects the butterflies

Fig. 3 Photograph of a monarch caterpillar by Tierra Curry.

Fig. 4 Photograph of a monarch chrysalis by Tierra Curry.

Fig. 5 Map of monarch migration by Curtis Bradley.

from excessive wetting and freezing during winter storms (Anderson and Brower, 1996) with surrounding forests acting as a screen to block severe wind (Brower et al., 2017). Because large diameter trunks have high heat capacity, mature trees have been compared to hot-water bottles that protect clustered butterflies (Fig. 7) from freezing temperatures (Brower et al., 2009).

Within the forests, butterflies are often located in arroyos near stream headwaters on moderately steep southwest-facing slopes (Slayback et al., 2007).

The oyamel forests are relicts from the Pleistocene that now have an island-like distribution. Additional species of trees in the overwintering grounds include primarily pines *Pinus* (Pinaceae) and oaks *Quercus* (Fagaceae). With the advancement of spring the butterflies move down arroyos into lower-elevation forests dominated by smooth-bark Mexican pine (*Pinus pseudostrobus*). Understory vegetation includes herbaceous and bushy species primarily in the aster (Asteraceae) and mint (Lamiaceae) families. Scientists have documented a total of 97 families, 337 genera and 694 species of plants in the overwintering forest area, 38% of which are endemic to Mexico (Cornejo-Tenorio and Ibarra-Manriquez, 2017). Local communities gather plants from the forest for food, medicine, fodder, fuel and to sell for income, making use of 213 plant species and 31 species of edible mushrooms (Farfán et al., 2007).

Fig. 7 Photograph of monarchs clustering on an oyamel fir trunk by Brett Hartl.

Western Migratory Population Overwintering Forests

Though some eastern and western monarchs overlap and interbreed, the vast majority of migratory monarchs west of the Rocky Mountains overwinter along the Pacific coast in a 1000-km stretch from Baja California in northwestern Mexico to Mendocino County in northern California. Historically monarchs have been recorded clustering at more than 450 coastal locations, but only about 30 sites still host more than 1000 monarchs annually ([Xerces Society for Invertebrate Conservation Western Monarch Count Resource Center, 2017](#)). Western monarchs can be found overwintering in forests within a few kilometers of the coast at <90 m elevation and in locations protected from severe wind and full sun such as shallow canyons or the sheltered side of hills ([Lane, 1993](#)).

Most of the western monarch's overwintering sites are now dominated by blue gum eucalyptus (*Eucalyptus globulus*) and red gum eucalyptus (*E. camaldulensis*) introduced from Australia in the 1850s. Despite the prominence of eucalyptus at overwintering sites, monarchs cluster disproportionately on native trees when present, which may provide more protection for the butterflies ([Griffiths and Villablanca, 2015](#)). Native tree species used for clustering include Monterey pine (*Pinus radiata*), Monterey cypress (*Hesperocyparis macrocarpa*), coast redwood (*Sequoia sempervirens*), western sycamore (*Platanus racemosa*), and coast live oak (*Quercus agrifolia*).

Principal Anthropogenic Stressors and Trends

Population Status and Trends

Scientists began estimating the size of overwintering monarch populations in the 1990s. In the mid-1990s the eastern migratory population numbered nearly 1 billion adults covering 21 ha of forest, but the population has since declined by more than 80%.

The overwintering population size is projected by multiplying the hectares of forest by the number of estimated butterflies clustered per hectare. Scientists have continuously calculated more approximate estimates of butterflies supported per hectare from 50 million butterflies ha^{-1} (Slayback et al., 2007) to 37.5 butterflies ha^{-1} (Vilsack and McCarthy, 2015) to 21.1 butterflies ha^{-1} (Thogmartin et al., 2017). In the winter of 2017–18, the overwintering monarchs covered only 2.5 ha, an estimated population of 52–93 million butterflies (Fig. 8).

The western migratory population has declined from 1.2 million overwintering adult monarchs in 1997 to fewer than 200,000 in 2017–18, and the 2018–19 count is expected to decline dramatically, numbering as few 30,000 total monarchs (Xerces Society for Invertebrate Conservation Western Monarch Count Resource Center, 2017).

Decades ago scientists warned that due to numerous threats the monarch migration could be at risk of collapsing, deeming it an “endangered phenomenon” (Brower and Malcolm, 1991). “Quasiextinction” is the likelihood that a population will decline below a threshold at which population recovery becomes impossible. The eastern migratory population is estimated to have a quasiextinction risk of up to 57% by 2036 (Semmens et al., 2016). Western monarchs have a quasiextinction risk of 72% by 2037 (Schultz et al., 2017).

Loss of Breeding and Migratory Habitats

Monarchs are threatened in their summer breeding grounds by a number of factors including loss of milkweed host plants to urban and suburban development, industrial agriculture, herbicides, and persistent drought (Center for Biological Diversity et al., 2014). They are vulnerable to widely-used insecticides including neonicotinoids which are toxic to young monarch larvae (Pecinka and Lundgren, 2015). Fragmentation and degradation of fall migratory habitat due to lack of high-quality nectar plants and insecticide-residues may also be contributing to monarch decline (Inamine et al., 2016).

Loss of Winter Habitat

Eastern migratory population forest loss

Because of their critical importance in sustaining the monarch migration, the Mexican government protected portions of the ever-green forests that provide the monarch’s over-wintering grounds as the Monarch Butterfly Biosphere Reserve (MBBR) in 2000, modifying earlier designations from 1980 and 1986 that were less comprehensive. After a small expansion in 2009, the MBBR now includes 13,555 ha in designated “core” zones where only activities that do not significantly alter the forest, such as scientific research, are permitted, and 42,704 ha in designated “buffer” zones, where logging, agriculture, and tourism are permitted (Manzo-Delgado et al., 2014).

Fig. 8 Graph of eastern migratory monarch winter population size by Tierra Curry, adapted data from World Wildlife Fund Mexico. Scientists have estimated that the minimum size of eastern overwintering monarchs for the population to maintain viability is 6 ha (Semmens et al., 2016).

While logging is prohibited in core zones, the land is owned and managed by various groups, including communal agricultural groups known as *ejidos* (6509 ha), indigenous communities (4953 ha), small private owners (1018 ha), and the state (708 ha) (Brenner and Job, 2006). Not all monarchs overwinter inside the reserve. From 2004 to 2014 the MBBR housed 14 overwintering sites, or colonies, on average (Vidal and Rendón-Salinas, 2014a), with nine colonies present in the winter of 2017–18; there were five colonies outside the MBBR boundaries during both time periods (Rendón-Salinas et al., 2018).

Deforestation and fragmentation threaten the butterflies both within and outside of the reserve. Even within the MBBR legal boundaries and core zones, habitat is being lost to illegal logging, authorized extraction, domestic harvesting, agricultural clearing, forest fires, storms, and disease and senescence of trees (Honey-Rosés, 2009).

Illegal logging within the MBBR is a persistent problem. The designation of protected zones in 1986 restricted traditional livelihoods of property owners without compensation; as a result, deforestation increased and more than 2000 ha of forest were degraded between 1984 and 1999 (Brower et al., 2002). The process of delineating new MBBR boundaries in 2000 was more inclusive of property owners, but deforestation has continued. From 2001 to 2012 in the core zones, more than 1500 ha fell to large-scale logging and 554 ha fell to small-scale logging (Vidal and Rendón-Salinas, 2014b).

Nearly 30,000 people live within the reserve's buffers, and more than 1 million people live around the reserve (Vidal and Rendón-Salinas, 2014b). Poverty levels are high and many people lack basic services and extract trees to meet needs for housing and fuel. Subsistence logging represents approximately one-fourth of the forest area that was lost and degraded from 2001 to 2012 (Vidal and Rendón-Salinas, 2014b).

While the problem is slowing, illegal logging remains a threat to the monarch's overwintering habitat (Honey-Rosés, 2009). In 2015 approximately 10 ha were illegally cleared, mostly on state land (Brower et al., 2016). From 2016 to 2018 two additional ha were illegally clear-cut (World Wildlife Fund Mexico, 2018).

The causes of illegal logging fall into several categories ranging from mafia-style gangs who steal timber to supply illicit trade, to authorized cuts that exceed allotments, and poverty-driven subsistence logging (Brenner and Job, 2006; Honey-Rosés, 2009; Navarrete et al., 2011). The sophistication of illicit logging operations has made it exceedingly difficult for communities and government officials to curtail, even with military assistance (Honey-Rosés, 2009).

Salvage logging, both legal and illegal, also threatens the monarch's overwintering habitat. Following a particularly severe winter storm in March 2016 that impacted 54 ha, the federal government authorized salvage logging in core zones. Salvage logging raises concerns from scientists that such activities will exacerbate damage and inhibit forest recovery (Brower et al., 2017; Leverkus et al., 2017).

Because overwintering butterflies have specific microhabitat requirements to avoid freezing, desiccating, or depleting their lipid stores, dense forest provides more protection, particularly during episodes of severe weather (Brower et al., 2011), making them exceedingly vulnerable to canopy reduction and forest thinning (Anderson and Brower, 1996). The extensive dense forest structure also captures moisture that in turn sustains the high-elevation cloud forests, making thinning a threat to the hydrological integrity of the ecosystem (Slayback et al., 2007).

Western migratory population forest loss

Loss of overwintering forests for the western migratory monarch population is also ongoing. Urban and housing development has destroyed dozens of monarch overwintering sites on the California coast. Overwintering groves are also threatened by tree senescence, restoration to remove exotic and aging trees, drought and winter storms (Xerces Society for Invertebrate Conservation, 2017). In 2017 a grove managed by California State Parks that had supported 9000 butterflies in 2013 was removed due to hazard concerns and in the following census only six butterflies were counted (Xerces Society for Invertebrate Conservation Western Monarch Count Resource Center, 2017). While long-term habitat restoration is planned and initiated, immediate mitigation strategies are needed for overwintering monarchs along the Pacific coast.

Changing Climatic Conditions

Monarch population dynamics and migratory success are intricately linked to weather events and to climate (Zipkin et al., 2012; Flockhart et al., 2017). Global climate change threatens the butterflies in their breeding, migrating, and overwintering ranges. The distribution and quality of milkweeds, their sole host plants, are strongly influenced by climatic conditions (Batalden et al., 2007; Stevens and Frey, 2010). In addition, monarch adult activity and larval development are dependent on temperature (York and Oberhauser, 2002; Saunders et al., 2018). Monarchs may lose part of their breeding range in the southern and western United States due to increasing summer temperatures and severe drought conditions that could be harmful to both the butterflies and their host plants (Zalucki and Rochester, 2004; Stevens and Frey, 2010). Environmental factors experienced during migration also affect the butterflies' ability to successfully overwinter and migrate north again in spring (Agrawal and Inamine, 2018).

Some monarch populations in Florida and other warm areas do not migrate and remain reproductively active year round, often in relation to the availability of tropical milkweed (*Asclepias curassavica*). Both widespread milkweed planting efforts and global warming could expand the range of tropical milkweed outside of its native range, thus preventing some monarchs from entering reproductive diapause and migrating. Nonmigrating populations of monarchs harbor more parasites than migrating populations (Satterfield et al., 2015). In addition, higher temperatures could change the chemistry of tropical milkweed and reduce its nutritional value for monarch larvae (Faldyn et al., 2018).

Multiple models predict that the monarch's current overwintering ranges will no longer maintain the narrow microclimatic window needed by the butterflies to remain in diapause and conserve lipid stores. Sáenz-Romero et al. (2012) examined the future distribution of oyamel fir trees and forecasted that by 2090 no suitable monarch habitat would remain within the current boundaries of the MBBR. One potential yet highly uncertain solution, assisted colonization of oyamel fir trees, would require the trees be transplanted to higher mountain ranges outside the MBBR where it is unknown if they would survive or if the butterflies would follow considering it is unknown which cues they use to choose suitable overwintering sites (Sáenz-Romero et al., 2012). The effects on forest community dynamics of assisted migration are also unknown and potentially detrimental to currently established species.

Climate-related factors are already driving loss of trees in the MBBR. The region has been in drought since 2008 which stresses trees, making them more vulnerable to diseases (Vidal and Rendón-Salinas, 2014b). Drought damaged nearly 4 ha of trees from 2017 to 2018 (World Wildlife Fund Mexico, 2018). Climate change could also increase the frequency of other threat factors including floods, strong winds, and forest fires (Vidal and Rendón-Salinas, 2014b; Brower et al., 2017).

Oberhauser and Peterson (2003) used ecological niche modeling to project monarch distribution onto future climate scenarios and found that winter conditions were likely to become increasingly unsuitable in the MBBR within 50 years due to an increase in the frequency of large-scale mortality events, such as winter storms. Large-scale mortality events killed millions of overwintering monarchs in the winters of 1980–81, 1995–96, 1999–2000, 2001–02, 2003–04, 2009–10, and 2015–16 (Brower et al., 2017). The threat of increasingly frequent and intense lethal winter storms to monarchs is exacerbated by decreasing population size driven by habitat loss in the summer breeding range.

The western migratory population's overwintering habitat in California is also threatened by global climate change due to warming temperatures, drought, storm events, fires, and tree diseases (Xerces Society for Invertebrate Conservation, 2017; Fisher et al., 2018).

Conservation Strategies and Challenges

Safeguarding the Monarch Butterfly Biosphere Reserve

Supporting local communities

To protect the monarch's overwintering forests in Mexico, perpetual enforcement is necessary along with support for local residents. The forests not only harbor monarchs, they are also the source of livelihood for people whose primary economic activities are agriculture, ranching, and harvesting of forest products. As such, efforts that support monarch conservation must also support and empower local communities through mechanisms that promote a sustainable economy and curtail illegal forest uses. Ongoing programs are required to alleviate poverty and unemployment, engage property owners in management decisions and provide adequate security against armed illegal loggers.

Successful community-based conservation often requires coordination and cooperation between local institutions and people, governmental agencies, and nonprofit organizations (Romero-Brito et al., 2016). The necessary cooperation can fall short in and around the MBBR, as governmental and local monitors have been underequipped. Community patrols may lack basic supplies such as warm clothing and communication devices, and community guards have been injured by gunfire from illegal loggers (Tucker, 2004; Mexico News Daily, 2016). Community enforcers may also not receive adequate support from the state or federal government as there are instances of apprehended poachers being released without consequence (Tucker, 2004; Mexico News Daily, 2015).

Though the challenges are daunting, much progress has been made in reducing large-scale illegal logging in the MBBR via law enforcement, payments to *ejidos*, and efforts to empower local communities and provide incentives for forest protection (Vidal and Rendón-Salinas, 2014b). Payment for Environmental Services (PES) programs have helped reduce deforestation in the MBBR by strengthening community participation and supporting sustainable alternatives to timber extraction (Manzo-Delgado et al., 2014; Ramírez-Reyes et al., 2018). When the reserve boundaries were reformulated in 2000 to include input from affected residents, the Monarch Butterfly Conservation Fund, a PES-like program, was established to compensate communal land owners in the core zones for forfeited timber rights and for areas of conserved forests (Honey-Rosés, 2009; Honey-Rosés et al., 2009). The fund has also provided compensation to communities harmed by illegal logging via support for community-based enforcement efforts (Honey-Rosés et al., 2009).

Because the monarch spans North America and people in the United States and Canada benefit from overwintering habitat protected in Mexico, international investment by governments could help support impoverished communities who have yielded their land-use rights (Semmens et al., 2018). Pesticide corporations that degrade monarch breeding habitat in the United States and Canada could also contribute funding to protect overwintering grounds to compensate for drastic reductions in common milkweed (*Asclepias syriaca*) in croplands (Brower et al., 2012). Ultimately, a sustainable local economy must be established that creates more opportunities for residents without reliance on timber extraction.

Tourism

From November to March thousands of tourists visit the forests to observe the overwintering phenomenon; the Mexican government reported 230,000 visitors during 2017–18. Community groups collect fees for entrance, parking, tour guides and horse rides, and sell food and souvenirs. Travel agencies in Mexico City and Morelia arrange day tours to the sanctuaries, though some visitors stay overnight in towns including Angangueo, Ocampo, Valle de Bravo, and Zitácuaro. Because nearly half of visitors arrive on bus tours, the economic benefit to local communities is reduced, hindering sustainable regional development (Brenner and Job, 2006). The direct annual income from tourism is estimated to be \$2.2–\$2.8 million U.S. (Brenner and Job, 2006; Semmens et al., 2018).

Tourism provides important benefits but can also threaten the forest and butterflies it supports. For example, tourists can disturb butterflies, causing them to fly and deplete lipid stores, decreasing their ability to survive the winter and the northward migration (Vidal and Rendón-Salinas, 2014a, b). Researchers have issued an urgent call to improve tourism management so that it ultimately contributes to long-term monarch conservation while improving local social and economic conditions (Vidal and Rendón-Salinas, 2014a, b). Tourism to the MBBR has great potential for supporting forest protection if it provides direct benefit to the local economy (Brandt and Buckley, 2018).

Restoration

Degraded areas in forests in and around the MBBR are recovering due to active restoration efforts, reduced logging and grazing pressures, postfire recovery, and abandonment of agricultural areas (Manzo-Delgado et al., 2014; Honey-Rosés et al., 2018). The reserve receives funding from numerous sources for reforestation efforts, and many areas are demonstrating resiliency and natural recovery (Honey-Rosés et al., 2018). Like tourism, restoration and management initiatives could be used to bolster financial and livelihood opportunities for local residents.

Safeguarding the Monarch's Future

Following decades of concern about mounting threats to the monarch from pesticides and habitat loss, in the winter of 2013–14 the eastern monarch's overwintering population dropped to only 35 million butterflies covering only 0.67 ha of forest, down from an estimated 1 billion covering 21 ha 20 years prior. This precipitous decline raised grave concerns about the butterfly's future and catalyzed further conservation efforts.

The presidents of Mexico, the United States, and Canada committed to saving the monarch's migration at summits held in 2014 and again in 2016. At the 2016 summit then-president of Mexico Enrique Peña Nieto said that the monarch's pilgrimage shows how the three countries are intertwined. Then-U.S. president Barack Obama called the monarch "spectacular" and pledged to make sure that future generations get to see them.

In August 2014 the Center for Biological Diversity, Center for Food Safety, Xerces Society for Invertebrate Conservation and Dr. Lincoln Brower petitioned the U.S. Fish and Wildlife Service to protect the butterfly as a threatened species under the Endangered Species Act. The service issued a positive finding on the petition and launched a status review that will lead to a decision on the butterfly's protection in 2019.

The Committee on the Status of Endangered Wildlife in Canada in 2016 recommended that the monarch be protected as an endangered species. The Minister of the Environment and the Canadian Endangered Species Conservation Council are now deciding whether to add the butterfly to the country's endangered species list. In Mexico monarchs are classified as a species subject to special protection.

The MBBR was designated by the United Nations Educational, Scientific and Cultural Organization (UNESCO) as a World Heritage Site in 2008 due to its outstanding biological value. In 2015 a coalition of conservation groups petitioned UNESCO to designate the reserve as a "World Heritage Site in Danger" due to the population decline of monarch butterflies. The World Heritage committee is evaluating the designation and has asked the United States and Canada to provide information on monarch conservation status in the breeding range.

At least five international conferences have now been held on monarch conservation and biology to share knowledge, advance conservation and sustainability goals, and to establish research priorities. Scientists are currently working to further evaluate threats to the butterfly in its breeding, migratory and winter habitats as well as working with citizen scientists to map the entire flyway, including currently unknown paths between Texas and the overwintering grounds. Studies are also underway to better understand how monarchs navigate to overwintering grounds. This knowledge would help develop strategies to mitigate loss of forest habitat due to climate change.

Globally, monitored invertebrate populations have shown a 45% decline in mean abundance since 1970 (Dirzo et al., 2014). Populations of many pollinators are in decline in North America and Europe including many species of butterflies. The monarch is uniquely positioned as a flagship species for invertebrate losses due to its familiar and cherished status and allies across the social and political spectrum.

Migrating monarchs have been described as "the personification of happiness" (Lane, 1993, p. 341) and as a "river of orange sunshine" (Shapiro, 2013, p. 3). The widespread attention this charismatic insect has harnessed from the media and policy makers is certainly cause for hope for the beloved butterfly's future. If this passion translates into pesticide reform, action to combat global climate change, and ongoing protection for the monarch's overwintering forests, then future generations will have the opportunity to marvel at the winged-wonder's spectacular migration.

Abstract

Forests are an integral element of life on earth. Providing oxygen to breathe, watershed protection, erosion control, carbon storage, and opportunities for people to connect with nature. Science warns us that at the rate forests are being destroyed, humans will alter the planet so significantly, that many lives (human and other species) will be extirpated. Recognition of the true value of forests, for their carbon storage function, is driving global agreements and policies to promote emissions reductions from land use across all biomes, but particularly in the tropics. Sizable levels of financial support have been directed at reducing emissions from deforestation and forest degradation, in the scope of USD 1.1–2.7 billion per year. But is this enough? This level of investment is still dwarfed by income from timber, agriculture, mining and palm oil cultivation—key drivers of tropical forest loss. We describe opportunities for reducing emissions from deforestation and forest degradation, discuss risks in measuring emissions reductions and draw attention to key political, social and environmental challenges from a regional perspective of Southeast Asia; a region in the spotlight for the mass expansion of oil palm plantations and polluting wildfires.

Introduction

Unprecedented and rising concentrations of carbon dioxide (CO₂), methane and nitrous oxide in the atmosphere that are resulting from energy production, agricultural output and industrial activity, are trapping heat in the lower atmosphere; causing the phenomenon of climate change. In 2015, parties to the United Nations Framework Convention on Climate Change held in Paris (COP 21) agreed that limiting global warming in this century to well below 2 °C and as close to 1.5 °C as possible to pre-industrial levels (UNFCCC, 2015) would be the most optimistic climate scenario to target. Moving to alternative energy sources could be slow, and fossil fuel burning accounts for the majority of emissions (Houghton et al., 2015). Four years post-Paris, the world collectively remains a long way from meeting these emissions targets. Short-term emissions reductions can be achieved from protecting, restoring and better managing tropical forests, which could reduce half the carbon emissions required to limit atmospheric warming to 2 °C and the carbon benefits would be relatively fast (Houghton et al., 2015). Consequently, it is widely understood that global agreements to mitigate climate change must include policies to reduce emissions from land use in the tropics. Forests are estimated to cover approximately 4 billion hectares of Global land area, according to the Forestry and Agriculture Organization of the United Nations (FAO). Of this, tropical forests represent approximately half of all forests, more than any other forest type. Around 9 million hectares of tropical forest cover were lost every year since 1990, representing the largest loss in any forest type for the period (FAO, 2015).

Strategies for Reducing Forest Carbon Emissions in the Tropics

Net emissions from land use change currently account for approximately 10% of anthropogenic carbon emissions. Reducing deforestation and degradation is one critically important way to lower global carbon emissions. Tropical forests are located mainly in Latin America, Southeast Asia and Africa. In Latin America, the highest rates of deforestation occur in Brazil, where 60% of the Amazon forest is situated. In Southeast Asia, the majority of deforestation occurs in Indonesia, followed by Malaysia. The majority of deforestation in Africa occurs in the Democratic Republic of Congo. Fig. 1 shows the total area of tropical primary forest cover loss for the top 10 countries in 2018 and the per cent increase from 2017. Brazil lost the most forest cover, followed by the Democratic Republic of the Congo and Indonesia.

Despite significant international efforts to reduce deforestation in the tropics, the success of these initiatives lies at the national and local level. National and local-level strategies and action plans to reduce deforestation include: reducing deforestation of natural forests and peatlands, sustainably managing oil palm and timber plantations, reduced-impact logging, restoration and improving the management effectiveness of existing protected forests.

Reducing Deforestation of Natural Forests

Global efforts to reduce emissions from deforestation in the tropics are largely driven by climate change policies. A study from 2008, reported that forest-based emissions could be cut by 75% by 2030 with international initiatives supported under the United Nations Framework Convention on Climate Change, such as REDD+ (Reducing Emissions from Deforestation and forest Degradation plus conserving, sustainably managing forests and enhancing forest carbon stocks; Eliasch, 2008). However, tropical forest cover loss has continued to escalate. In 2016, global tropical primary forest cover loss was the highest year on record since 2002. Declines occurred in 2017 and 2018, yet they are still among the largest forest loss years experienced this century (Fig. 2).

Southeast Asian forests are among the most ancient, diverse, carbon-dense and critically threatened of all forests in the world. Consequently, the region is a major focus of policies for reducing emissions. Regional initiatives to reduce deforestation include the Singapore Declaration on Climate Change Energy and Environment, which has mandated the Association of Southeast Asian Nations (ASEAN) members to:

promote cooperation on afforestation and reforestation, and to reduce deforestation, forest degradation, forest fires, including by promoting sustainable forest management, combating illegal logging, protecting biodiversity, and addressing the underlying economic and social drivers.

Agricultural production drives 73% of tropical forest loss worldwide, followed by urban expansion (10%), infrastructure (10%) and mining (7%; Hosonuma et al., 2012). A movement toward renewable energy has seen an increase in the production of biofuels, which unintentionally has had major consequences for emissions by contributing to an increase in tropical deforestation to grow

Fig. 1 Total tropical primary forest cover loss (in hectares) in 2018 for the top 10 countries. Source: Global Forest Watch, World Resources Institute, www.wri.org.

biofuel products. According to the European Commission, greenhouse emissions from biofuels are three times higher than biodiesel. Palm oil is a commonly used product to produce biofuels. While palm oil has been linked to catastrophic deforestation, it is difficult to detect a direct link between first and second generation of biofuels and deforestation at a global level due to limited availability of time series data.

Forest moratorium

In 2011, the Indonesian government issued a moratorium on the conversion of primary forests and peatland forests under Presidential Instruction (No. 10/2011), which aims to suspend the granting of new concession licenses for logging and forest conversion in primary forest and peatlands. Since its initiation, it was extended three times in 2013, 2015, and 2017—yet deforestation remained alarmingly high. One of the issues limiting the success of the moratorium in the first 6 years, was that local governments continued issuing licenses despite the central government prohibiting further issuance. In addition, the Presidential Instruction did not entail legal consequences for perpetrators. With a decentralized political system in Indonesia, sub-national leaders were able to issue local policies that undermined the moratorium. In 2017, the annual deforestation rate dropped by 60% in Indonesia, followed by another small decline in 2018; two of the lowest deforestation years in this century (Fig. 3). The 2017 annual deforestation rate of protected peat areas also dropped by 88% in Indonesia. Over a quarter of protected peatlands have pulpwood and oil palm concession areas within their boundaries, or licenses to establish them. The Indonesian Government implemented a land swap program to prevent further conversion in protected peatlands (see “Land Swaps” section).

Sustainably Managing Oil Palm and Timber Concessions

Oil palm and timber concessions are two major drivers of tropical forest loss in Southeast Asia. The majority of global palm oil consumed comes from tree plantations in Indonesia and Malaysia. In 2016, Indonesia produced 34,520,000 tonnes of palm oil, and Malaysia produced 17,320,000 tonnes. To meet the high global demand for palm oil and timber, primary forests across the Indo-Malayan islands of Sumatra and Borneo have undergone rapid transformation into expanses of oil palm and timber plantations. Borneo became a hotspot of deforestation in the late 20th century, with land clearing for oil palm and pulpwood plantations contributing to a 34% loss in primary forest cover between 1973 and 2015 (Gaveau et al., 2016). Of the 18.7 million hectares cleared during this period, 14.4 million hectares were in Indonesian Borneo (Kalimantan) and 4.2 million hectares were in Malaysian Borneo (Sabah and Sarawak), respectively.

Efforts to reduce deforestation from oil palm and timber production encompass a range of standards, certification schemes and policies driven by government, industry and non-government organizations (NGOs). For example, palm oil industry representatives and NGOs benchmark the performance of palm oil producers against a set of Certified Sustainable Palm Oil (CSPO) standards under the Roundtable on Sustainable Palm Oil (RSPO). Companies who comply with the CSPO standards around environmental and social sustainability, receive certification and can charge a premium on their products. The European Union, the third largest importer of Malaysian palm oil, have called for banning the use of palm oil as a biofuel by 2030. In 2018, European

Fig. 3 Total area of primary forest cover loss (in hectares) in Indonesia from 2002 to 2018. Source: Global Forest Watch, World Resources Institute, www.wri.org.

parliamentarians proposed to restrict imports of Malaysian palm oil-based biofuel within the union, with Norway the first to commit to banning palm oil biofuels from 2020. Government led initiatives include the palm oil moratorium issued in 2018 by the Indonesian President Joko Widodo. Under Presidential Instruction (No 8/2018) on the Delay and Evaluation of Permits and Elevated Productivity of Oil Palm Plantations, new permits for oil palm plantations were suspended for 3 years. During this time, the government is also seeking to review the current allocation of permits, of which some are located on land classified as “forest area.” Stemming from the Government’s commitment to reducing deforestation, the three-year palm oil moratorium is intended to address issues around overlapping tenures and licenses, and the rights of smallholders to equal partnership with large-scale plantations. Similar industry led initiatives are focused on sustainable forestry and tree plantations.

Reduced-Impact Logging

The extraction of timber from forests is one of the most widespread forms of tropical land use, with over 20% of humid tropical forests subject to log-harvesting. Reduced-impact logging (RIL) is a practice of timber extraction that adheres to guidelines aimed to reduce wastage and collateral damage during logging activities. Forests logged according to RIL methods have less initial carbon loss than conventionally logged-forests, and fewer years of carbon declines before they start recovering carbon. Guidelines include reducing road and landing pad construction impacts, and reducing collateral damage to remaining trees during extraction by directional felling and protection of water courses. Field studies across Southeast Asian sites found forests logged according to RIL methods saved 20% more carbon over 30 years than those logged using conventional log-harvesting techniques (Pinard and Cropper, 2000; Healey et al., 2000; Putz et al., 2008). Further emissions benefits can be generated from selective logging of forests where minimal disturbance occurs to peat hydrology. Despite the environmental potential of RIL, the practice is not widely implemented and furthermore, concerns remain about how environmentally sustainable it really is. For example, Zimmerman and Kormos (2012) contend that sustainable forestry management cannot be truly sustainable under current practices, due to increased management and training costs, and decreased harvestable timber volumes, associated with achieving sustainable high-value tropical timber yields. A key concern is the length of the cutting cycle, with some studies contending that 60 years is necessary for forest structure to recover to baseline conditions. Another concern is whether highly specialized biological interactions will recover post-logging (e.g., endemic tree species and pollinator interactions). However, an opportunity exists in locally-managed timber harvesting, which can successfully protect relatively intact tropical forest systems and promote sustainable livelihoods—if locally-managed forests are backed by national legislation (e.g., ratification of community land tenure). Selectively logged-forests are one of the less degrading of land use scenarios for carbon stocks and biodiversity observed in Southeast Asia, and can be equally as effective at reducing deforestation as protected areas (Gaveau et al., 2013).

Restoration

Carbon loss that has already occurred due to deforestation and forest degradation can be somewhat recovered by reforestation, where forests and their carbon stores, are assisted or allowed to recover. The restoration of tropical forests reduces net anthropogenic carbon emissions by accruing carbon above and below ground. Forest restoration can include replacing trees that have been cleared with new plantings or allowing the natural regrowth from seed banks, often on degraded land that was set aside for agriculture but is no longer under active management. Degraded or secondary forests can be restored for the purpose of fire prevention and biodiversity conservation (often with the aim of conserving key seed dispersers to aid seed dispersal). Successful restoration also benefits communities in terms of enhanced food security, improved air and water quality, climate change resilience, job creation, and more. Restoration can be on mineral or peat soils, below we discuss key differences.

Peat restoration

Tropical peatlands cover a global area of 44.1 million hectares, with 56% of these occurring in Southeast Asia, storing 69 billion tonnes of carbon (Miettinen et al., 2012; Page and Rieley, 2016). Tropical peatlands represent 11% of land in Indonesia and store up to 20 times more carbon than non-peat mineral soils. Their drainage and degradation is responsible for 5% of anthropogenic CO₂ emissions. Once drained, peatlands are highly susceptible to prolonged episodes of burning. The worst peat fire years in Indonesia occurred in 1997, 2006, 2009, 2012, 2013 and 2015. Emissions from the 1997 El Niño fires were equivalent of 13%–40% of annual global emissions from fossil fuels (Page et al., 2002). Although this was a particularly bad year for peat fires, it illustrates the magnitude of such an event. Again in 2015, the traditional burning practice widely used in Sumatra and Borneo for land clearing was exacerbated by a long drought period, causing wildfires to burn for 2 months and releasing 97% of the annual carbon emissions from Indonesia in those 2 months alone (Huijnen et al., 2016).

As a response to the forest fire crisis in 2015, the Indonesian government launched the Peatland Restoration Agency in 2016, which ambitiously aims to restore 2 million hectares of peatland in seven provinces (Riau, Jambi, South Sumatra, West Kalimantan, Central Kalimantan, South Kalimantan and Papua). Peatland restoration is expensive and requires substantial investment from private companies, where many concessions are located, as well as support from local communities. Peatlands are naturally wet areas, and to remove timber in these areas the wetland is firstly drained before the timber is accessible. Peatland restoration, therefore, can involve blocking canals to encourage flooding, rewetting these areas and then replanting. It is consequently much more expensive than restoration on dry mineral soils.

Land swaps

Also in response to the 2015 mega fires, the Government of Indonesia initiated a nation-wide peatland governance reform. As part of this reform, peatland was rezoned based on its ecological characteristics, into conservation or cultivation function. On peatland with conservation function, a permanent moratorium is applied in which only research, ecosystem protection and education are allowed. Over 200 forest plantation concessions overlap with the new “peat with conservation function” designation, prohibiting the concessionaires from cultivating the land. As a form of compensation, a land swap policy was prepared by the Ministry of Environment and Forestry (MOEF) for timber concessionaires whose plantations overlap with protected peat systems by more than 40%, offering them less fire-prone land in exchange. A map was released showing the location of the new land swap sites in Kalimantan, Sulawesi and Papua that are asserted as having low-quality forest cover. A civil society coalition found that 40% of the land proposed as suitable for swaps contains primary or secondary forest. Other potential risks of the policy include the potential for concessionaires to dodge their obligations to restore degraded peatlands under the guise of taking the land swap avenue, and stirring further sociopolitical conflict if the lands proposed for swaps are inhabited or managed by local people.

Improving the Management Effectiveness of Protected Areas

Protected areas aim to safeguard natural assets and conserve biodiversity, yet they are not spared from global patterns of forest loss and degradation. Though the proportion of total area under protection is increasing, rising from 8% in 1990 to 15% in 2019, the land inside protected areas remains exposed to threats and in some places the biodiversity inside protected areas is declining. Curtailing illegal deforestation in protected areas represents a significant opportunity for reducing emissions from land use change. Adequate law enforcement and staff, infrastructure and equipment is dependent of funding, which has historically been poor in tropical nations. Increased investment in protected area management resourcing, education and training programs could substantially lower the illegal deforestation, logging, burning and agricultural encroachment that are common in parts of Southeast Asian protected areas. A significant opportunity for climate mitigation and biodiversity conservation lies in abating the high level of illegal forest loss and the carbon emissions predicted to occur in the future if the current pace of tropical forest loss continues. Between 2000 and 2010, approximately 2% of forest cover was lost every year illegally, inside boundaries declared by the International Union for the Conservation of Nature (IUCN) as protected. Projections for the next 30 years, are that an additional 414 million tonnes of carbon would be emitted from Indonesian protected areas if the 2000/10 pace of illegal deforestation continues (Graham et al., 2017).

Small-scale encroachment for agriculture and plantations, as well as illegal timber harvesting, are some of the drivers of forest loss inside park boundaries. A range of socioeconomic and political conditions underlie these activities, such as local migrants moving into protected areas, local governments recognizing villages and communities within National Park boundaries, inadequate resourcing, National Park agencies lacking the capacity and authority to enforce their mandates and a lack of support from local government for national policies. An example of encroachment can be seen in Kutai National Park in the province of East Kalimantan, Indonesian Borneo, which has areas that are occupied as villages and oil palm plantations (Fig. 4).

History of Development: From RED to REDD to REDD +

Payments for Ecosystem Services (PES) are a type of market-based instrument that provide economic incentives to stakeholders for retaining and improving the size or quality of natural assets resulting in improvements to ecosystem services (e.g., providing carbon credits to landowners for conserving forests). REDD + is the most prominent international financial mechanism currently being practiced for conserving tropical forests and reducing carbon emissions from forestry and land use in the tropics. REDD + facilitates monetary incentives to developing nations that preserve or enhance the carbon storage function of natural forests. For example, Norway has significantly contributed to REDD + programs in Indonesia, as well as Bolivia, the Democratic Republic of the Congo, Panama, Papua New Guinea, Paraguay, Tanzania, and Vietnam. The scheme aims to offer both environmental and economic benefits to host countries; including improvements in the long-term natural resource pool and financial benefits to local forest-dependent communities.

REDD + was first officially proposed in 2005 by a group of 15 developing countries led by Papua New Guinea and Costa Rica known as the Coalition for Rainforest Nations (www.rainforestcoalition.org). When REDD + was more formally discussed in 2007 at the COP13 in Bali, it was solely concerned with providing a cost-effective solution to reducing emissions from deforestation (RED) and only later grew to include forest degradation (becoming REDD). In 2008, the idea of including the conservation, sustainable management and enhancement of forest carbon stocks was discussed and REDD “+” was introduced. This was an important developmental milestone as it opened up two activities: (1) channeling more funds to improve the management effectiveness of protected areas; and (2) promoting the restoration of degraded forests. By 2010, it was recognized that REDD + needed some sort of protection against perverse outcomes for local forest-dependent communities and biodiversity, resulting in the inclusion of “safeguards” in the Cancun agreements and later refined in Paris in 2015. These are sometimes referred to as “non-carbon outcomes.”

One of the key objectives of REDD + is to enhance the wellbeing of local communities that are hosting projects. Community Forest Management is defined as the use, management and conservation of forests by communities, whether ownership is held by the community or by a state agency with involvement from the community. Community-managed forests are a common and growing governance arrangement in developing countries. Globally, approximately 15% of forests are owned or assigned to indigenous peoples and local communities. Some scholars argue that community forest management is a win-win scenario for reducing deforestation, conserving biodiversity and contributing positively to local community livelihoods. Indonesia has at least

Fig. 4 Oil palm plantation inside enclave village in Kutai National Park, Indonesian Borneo. Credit: Laely Nurhidayah.

four different types of community forests, including: village forests (*Hutan Desa*), community forests (*Hutan Kemasyarakatan; HKM*), *Adat Forest*, *Community Based Plantation Forest*, and *Private forest (Hutan Rakyat)*.

Results-Based Finance via REDD+

To qualify for results-based finance via REDD+, countries must have demonstrated they have a national strategy or action plan for reducing forest-based emissions, a system for monitoring and reporting on emissions, a baseline (reference level) against which emissions reductions are measured, and a safeguard system to protect against confounding environmental or social issues stemming from REDD+ projects (Seymour and Busch, 2016). As the outcomes of REDD+ are measured against reference levels, it is necessary to adopt a transparent and fair methodology in calculating these benchmarks. Countries can access REDD+ “readiness” funding to support the development of these requirements. A key difference between REDD+ and other financial mechanisms such as the Clean Development Mechanism (cdm.unfccc.int), is that REDD+ relies on results-based finance and can be funded through bilateral or multi-lateral agreements or the carbon market. Previous schemes have had less flexibility in their mode of financial operation. The Paris Agreement allows for the “international transfer of mitigation outcomes” meaning developed countries can purchase carbon credits through REDD+ to offset their emissions.

REDD+ finance in the first 10 years of implementation has almost solely been from voluntary commitments from donor countries. However, in 2019 Norway announced its first results-based payment to Indonesia as part of their REDD+ agreement, in recognition of a 60% drop in forest loss from 2016 to 2017. Global estimates of finance being pledged or already committed to REDD+ are USD 1.1–2.7 billion per year, compared to the estimated USD 15 billion per year required (Centre for Global Development; Olesen et al., 2018). The Forest Carbon Partnership Facility (forestcarbonpartnership.org), with the World Bank as trustee, has also committed US\$399 million in readiness activities to fund training and monitoring activities.

Challenges of Measuring Emissions Reductions

A large amount of criticism has been directed toward the process of measuring, reporting and verifying (MRV) carbon reductions to ensure that only “real” carbon reductions are being incentivized. These challenges include: additionality (paying to reduce emissions that would not have occurred under the business-as-usual scenario), permanence (emissions reduced now that are offset by increased emissions in the future) and leakage (emissions reduced in one location that are shifted to another location without the same controls). There are two methods commonly applied to carbon accounting, both have risks. A historical approach, that assumes past rates of deforestation will continue, favors countries shifting from high to low deforestation and therefore has the risk of encouraging intensified deforestation prior to REDD+ implementation. Simulated models have also encountered distortions in measuring emissions reductions, as modeled predictions of future land cover change have been shown to have very high error rates, particularly when regional trend data are applied to small local sites (Pontius et al., 2008). The definition of a forest is also very different, depending on who is providing the definition. Today, there are known to be >800 official definitions of forest. For example, the Forestry and Agriculture Organisation (FAO) apply a definition of tree cover of >10% to measure forests. It is important that REDD+ hosts and donors agree on the type of land use and land cover change that qualifies for incentives.

Where Are We Now?

A review led by the Centre for International Forestry Research (CIFOR) has synthesized the learnings from more than 350 REDD+ projects for the 10-year period till 2018 and reviewed progress in lowering deforestation and forest degradation, reducing emissions, improving livelihoods and strengthening forest governance in developing countries (Angelsen et al., 2018). There are three key messages:

- i. REDD+’s distinguishing design feature of results-based payments remains yet to be tested at scale. Funding has been less than anticipated and is mostly from voluntary commitments rather than via the carbon market.
- ii. REDD+ has helped forests gain a prominent narrative across the world stage at both political and community level. This attention has contributed to significant advancements in forest and carbon monitoring capacities, stakeholder involvement and programs to address indigenous and community land rights for many nations across the tropics.
- iii. Further work needs to be done to better integrate forestry and other land use opportunities into national development and climate mitigation policies.

Concluding Remarks

The significant climate mitigation potential of REDD+ is yet to be utilized at a cost-effective global scale that can influence future emissions and climate trajectories; yet momentum is building in some regions. Despite the negative press attracted by the growing

palm oil industry and polluting forest fires, Southeast Asia has made substantial progress in identifying and addressing key challenges of reducing emissions from deforestation and forest degradation. Recent initiatives in Indonesia include the government led primary forest and oil palm moratoriums, the land swap policy, the peatland restoration program, support for community managed forestry and the high volume of REDD+ readiness activities underway. Our case studies below highlight a couple of these recent initiatives. The first case study compares the range of costs and benefits that can be achieved through REDD+ activities when spatial context is considered, and the second case study emphasizes the importance of aligning activities with local initiatives to address land access inequality issues. Looking forward, the decreasing rate of deforestation seen in 2017 and 2018 in Indonesia provides some reason for cautious optimism that these initiatives are starting to work.

Case study: Comparison of costs and benefits of REDD+ strategies

The range of opportunities financed through REDD+ is diverse and not all activities deliver equal carbon incentives (Graham et al., 2016). Restoration of tropical Southeast Asian forests has high carbon incentives, which makes it a cost-effective strategy to implement (per tonne of carbon reduced) and has large scope, due to the vast areas of degraded land that are candidate sites for reforestation. Based on past deforestation rates, reducing illegal deforestation could generate large carbon gains, if projects are targeted to deforestation hotspots and carbon rich forests (e.g., peatforests). The costs of this strategy include better resourcing of protected areas, such as employing more law enforcement officers and erecting clear boundary markers and fences, while the incentives include the carbon benefits alongside biodiversity, tourism and, if well managed, local livelihoods through non-timber forest economies.

Environmental threats, as well as the carbon benefits and costs of implementing conservation strategies are influenced by the spatial context in which they occur. Site-specific factors, including terrain, carbon density, distance to markets and soil type influence the costs and benefits of conservation strategies. A study by Graham et al. (2017) estimating the costs, benefits and scope of REDD+ in Indonesia found the range of costs varies significantly for all strategies. For example, reducing deforestation from oil palm and timber plantations had high potential carbon gains, and some cost-effective locations in areas where oil palm plantation licenses have been granted on unproductive land or peatlands.

Aside from financial costs and carbon benefits, important ecological considerations include the carbon-biodiversity trade-offs of REDD+ activities. For example, biodiversity benefits from restoration can be large where regrowth is promoted on degraded forests, but one of the most serious risks to biodiversity is afforestation, which could lead to carbon-rich plantation forests being valued over biodiverse, low-carbon grasslands. Social concerns of REDD+ include the risk of “fortress conservation” in which the priorities of international investors are privileged over those of local forest users. Community opposition and poor knowledge and communication have been seen to stall project development. In the forest frontier district of Kapuas Hulu, Indonesian Borneo, communities resisted to engage with proponents due to uncertainty about the terms of inclusion and future rights to resources under proposed governance models. Such resistance could significantly delay projects and incur large additional costs.

Case study: Social Forestry in Indonesia

In Southeast Asia, a key strategy to reduce deforestation and improve tenure security for forest communities is through national social forestry programs. Social forestry (or community forestry) is a strategy to restore community access to forested land. According to the Association of Southeast Asian Nations (ASEAN) Social Forestry Network, social forestry has three objectives: (1) environmental conservation in the form of sustainable forest management; (2) indigenous people’s land rights and local knowledge; and (3) community benefits. These traits align with REDD+, which has played an important role in financially supporting the advancement of social forestry in the region. Cambodia, Indonesia, Myanmar, the Philippines, Thailand and Viet Nam have established national targets for the area of land to be allocated to local people under their social forestry programs. If achieved, this would result in over 30 million hectares of forest land being managed under social forestry programs in the ASEAN region by 2030.

The ASEAN members established a Social Forestry Network in 2005 to facilitate knowledge exchange and promote community involvement in social forestry. Each ASEAN member state has developed its own definitions and modalities to implement social forestry, therefore, social forestry takes different forms, depending on national laws and policies, the forest type, and the aims and objectives for engaging them in forest management. The definition of forest adopted in Indonesia was created as a mechanism of state capture of land and natural resources (Astuti and McGregor, 2017). The issuance of the Basic Forestry Law in 1967 was followed in the 1970s with a map that divides land in Indonesia into two categories: forest land and non-forest land. Forest land falls under the authority of the Ministry of Forestry and non-forest land under the National Land Agency.

The issue of land grabbing is a national priority that the Indonesian Government is aiming to address through their social forestry program. According to the Central Bureau of Statistics, 60–70 million people live in or around forests. Yet the control or ownership of the majority of forests is with a small group of stakeholders: pulp and paper operators, and oil palm and logging concessionaires. The national Social Forestry Program, launched in 2014, aimed to distribute 12.7 million hectares of forested land under President Joko Widodo’s regime from 2014 to 2019. However, tenure conflicts resulting from the issuance of forestry plantation concessions has resulted in only a fraction of this area currently planted, with the remaining lands being contested with local and indigenous communities. Land tenure conflicts typically arise when local people have a customary belief in ownership of the land, without a written deed. Communities that are required to apply to lease land that they have managed for a long time, can feel disempowered. Despite significant challenges, there are some examples of social forestry schemes working well. Lampung Province on the Indonesian island of Sumatra has been hailed a model of social forestry. For nearly two decades, a government scheme has granted the community rights to use and manage forest resources, and the social and environmental benefits include: reduced rates of land clearing, improved overall community welfare and reduced inequality within the community. Similar reduced deforestation evidence has been documented from social forestry schemes in Indonesian Borneo.

Abstract

Aggressive logging of public old-growth forests in the Pacific Northwest came to an abrupt halt in 1992 due to litigation involving the federally threatened northern spotted owl (*Strix occidentalis*). Much has been written about the ensuing crisis, but not about how Forest Service officials resolved it in ensuing years. The effort to create a new forestry model relied on applying important holistic concepts to restore biological function to Douglas-fir (*Pseudotsuga menziesii*) forests. The crisis also necessitated reengineering inclusive social processes to restore hope to disenfranchised parties. A successful new social contract emerged for managing public lands stuck in gridlock that has proven effective, durable, hopeful, and resilient.

It had the feeling of a meat locker door clunking shut behind you... and then hearing a bolt lock into place. Judge Dwyer had spoken. The good old days of unmitigated clearcut logging were gone forever.

In 1991, a ruling from federal district judge William Dwyer stopped the Forest Service from cutting timber from forests inhabited by the northern spotted owl. The injunction clamped the jugular of federal timber that reliably fed timber mills in the Pacific Northwest, sending a deep shudder through the industry that depended on these forestlands for raw material. The end had finally come to the decades-long liquidation of old-growth forests.

Prior to Judge Dwyer's ruling, the Forest Service had inexorably, incrementally sought to tame the vast and valuable forests of the Pacific Northwest. Aggressive logging of public land rested on a foundation of a growing nation's demand for wood. And the nation trusted the Forest Service as long as its policies seemed consistent with public values. But public values can change. Distrust can grow.

Dwyer's judgment concluded a hard-fought legal and public relations campaign by a determined environmental community that viewed government management of their public lands with skepticism, cynicism, and outrage. Few people accepted sweeping vistas dominated by clear-cuts and new roads. Instead, they valued naturalness, clean water, abundant fish and wildlife, and a deep sense of connection with the land. They anguished at what the Forest Service was taking from the forest at the expense of current and future generations.

You can plant all the trees you want, but you can't make a forest. That's God's business. Environmental groups used the northern spotted owl as the arrow to successfully pierce bureaucracy's armor. The agency's own planning regulations required it to protect the viability of wildlife, including owls. Judge Dwyer based his ruling on convincing evidence from the plaintiffs that the Forest Service was cutting down the very same old-growth forest habitat that was essential for owl viability. Using Forest Service scientific research that demonstrated population declines, environmental groups proved that federal laws did not allow the agencies to threaten the owl's viability. In this, they scored one of the most significant legal victories in the battle between commerce and the environment.

Siuslaw National Forest, where I served as supervisor from 1992 to 1999, sat in the crosshairs of the spotted owl controversy. In response to the ensuing chaos and crisis, the Siuslaw forged a new vision and strategy for managing federal forestlands. This new Siuslaw model uses management approaches that nurture, rather than eliminate, mature and old-growth forests and their associated fish and wildlife habitats. It also reflects the values and aspirations that most people in the region have for their national forests. I say most, because some traditionalists within the Forest Service, and certainly the timber industry, remain opposed.

The Siuslaw, located in Oregon's highly productive Coast Range, became the antithesis of the kind of industrial forestry practiced on national forests for decades. What if all national forests undertook a thorough and fundamental rethinking of how to achieve the basic mission of stewarding public lands in the face of changing values and circumstances, such as climate change?

I confronted the wrenching challenge of reframing the mission subsequent to the owl crisis. We made profound changes to forest management that produced real triumphs. Yet relatively little has been written about the social strategies and consequences associated with the intense biological and political fallout.

In winter, dense fog often cloaks Oregon's Willamette Valley. After several days of oppressive grayness, people yearn for a glimpse of sunshine. Similarly, the loss of hope—and onset of despair—enveloped the Pacific Northwest region, and this remains one of the

great, yet subtle, casualties of the spotted owl crisis. Restoring ecological function to the great Douglas-fir forest region, but also meaningful hope to the people who lived, worked, and managed these majestic forests became essential. Success ultimately turned on achieving strong and enduring consensus among various factions and interests that had formerly feuded over national forest logging policies. Though the Forest Service had lost its luster as a “trusted broker” (if it had ever enjoyed such prestige), Siuslaw National Forest staff needed to engage interested parties, invite them to link arms and strive jointly to address our bleak future head on.

Which Comes First—Chicken or Egg?

An important consideration confronted agency leaders: Should we first declare a vision and use public engagement processes to gain consensus, or should we convene people around a blank slate and collectively create a vision from scratch?

This has profound implications for agencies managing public lands. Decades-long controversy over clear-cutting old-growth forests had plagued the Forest Service in particular, with precious little nuance left to be cussed and discussed. In response to Dwyer’s judgment, President Bill Clinton, accompanied by Vice President Al Gore and most of his cabinet, convened a 1-day forest conference in Portland OR in April 1993 to review the “state of knowledge” and then determine how best to proceed in the face of a virtual shutdown of a major regional economic driver. Clinton closed the conference by tasking forest land agencies to develop a solution within 90 days. A hastily convened cluster of scientists completed this Herculean task on time. This draft “Clinton Plan” was published and subjected to public review and comment, and ultimately became the “Northwest Forest Plan” (NWFP) to govern future management of public forests on over 10 million hectares of federal agency lands. The NWFP embodied a complex set of rigorous standards and guidelines, but I did not view it as a recipe to be followed, lock-step. I saw the NWFP as a fairly detailed black-and-white sketch, with requisite color and local detail to be filled in based on our unique conditions.

The NWFP, in my view, adhered to the “vision, then consensus” model cited above. Scientists had distilled research findings and management principles to create architecture—a vision—to move forward. The hope was that the NWFP would be viewed as a robust and trustworthy “solution”; therefor combatants would lay down their weapons, and consensus would engender lasting peace. Hope may spring eternal, but in this case reality prevailed.

Context

Siuslaw National Forest, established in 1907, has a history of aggressive timber harvest, mostly in the post-World War II era. Siuslaw timber management mirrored industrial forestry—clear-cut the standing timber, burn logging slash to prepare for planting a dense monoculture of Douglas-fir, spray herbicides to eliminate competition, and (often) plant genetically superior seedlings, then fertilize to give it all a boost. The Siuslaw spent more money per hectare than any other national forest because it generated the most wood and revenue per hectare.

About 1990, Siuslaw timber production began to decline precipitously in the aftermath of lawsuits and legislation. Three pivotal factors affected the Siuslaw: spotted-owl population declines; then conflicts over the marbled murrelet (*Brachyramphus marmoratus*) (a small oceanic bird that nests in big coastal conifers); and finally plummeting Pacific salmon (*Oncorhynchus* spp.) stocks.

An essential first element of problem resolution is problem recognition. The real message from Judge Dwyer was that institutional denial and resistance to changing traditional forest management prevailed at the highest levels of the Forest Service and permeated all levels of leadership. Judge Dwyer’s 1991 opinion stated: “The problem here has not been any shortcoming in the laws, but simply a refusal of administrative agencies to comply with them. This invokes a public interest of the highest order, the interest in having government officials act in accordance with the law. More is involved here than a simple failure by an agency to comply with its governing statute.... The most recent violations of the NFMA (National Forest Management Act) exemplifies [sic] a deliberate and systematic refusal by the Forest Service and the Fish and Wildlife Service to comply with the laws protecting wildlife. This is not the doing of the foresters, rangers, and others at the working levels of these agencies. It reflects decisions made by higher authorities in the Executive branch of government.”

Former Forest Service chief Dale Robertson was among those found by Dwyer to have deliberately and systematically refused to comply with laws protecting wildlife. Robertson had been forest supervisor of both Siuslaw and Mt. Hood National Forests early in his career. Remarkably, Robertson assumed leadership of the Siuslaw at the very young age of 31, indicating that superiors recognized his great potential. Robertson, highly respected throughout the Forest Service, continued to rocket up through the agency and became chief at 47. He and other leaders knew the Pacific Northwest forests well. I think they consistently maintained timber harvest at high levels in the well-intended belief that this policy best served the interests of the public and the agency.

I could see that the policies and actions of these leaders laid bare a deep schism between the past and the future—forest management as it had been done and what it needed to become. The goal for decades had been to maintain the annual timber harvest total for all national forests at a level of about 11 billion board feet (~26 million cubic meters). Thus, Forest Service leaders managed owl issues to minimize disruption of timber production. Timber harvest transcended even legally required protection of the owl and other wildlife. The lawsuit successfully demonstrated that this policy was both illegitimate and illegal. A different approach was needed.

The same schism evidenced itself throughout the nation at the field level. Siuslaw managers issued their forest plan in 1990, just before I arrived in late 1991, having taken almost 10 years to complete the effort. The scientific basis for protecting the owl had started with researcher Eric Forsman's 1976 master's thesis, completed while he was a graduate student at Oregon State University. Forsman had become interested in the owl after observing them in the Corvallis watershed (a source of drinking water for the town), which lies along the eastern fringe of Siuslaw National Forest. He described the critical link between late-successional (mature) forests and the owl's habitat needs. Eliminate these forests, his research suggested, and you eliminate owls. In 1987, the Forest Service hired Forsman as a research wildlife biologist at the Corvallis Forest Sciences Lab.

If Forsman's research had an embedded message for the Forest Service and its timber management practices, one would think it would have been heard most clearly in Corvallis. Yet dedicated adherence to timber production marked the 15-year period between 1976 and Dwyer's judgment in 1991, both on Siuslaw National Forest and throughout the Pacific Northwest region.

The owl controversy had become white-hot by the time Siuslaw managers released their forest plan just prior to Dwyer's injunction. The plan established an allowable timber sale quantity of about 0.5 million cubic meters per year, a reduction from the 0.75 annual sale level throughout the 1980s. Many thousands of jobs and billions of timber dollars hung in the balance. Although the owl issue had already begun to threaten traditional timber policy and harvest levels, the Siuslaw plan made a very clear statement that timber occupied the seat of highest priority, and that clear-cutting of mature timber would continue. Minimal measures—the least possible—would be taken to protect the owl.

Numerous other plans for national forests in owl habitat followed the same thinking as the Siuslaw's. The Forest Service was doubling down on its bet against owls.

But Dwyer's injunction dramatically changed all this. As the new Siuslaw forest supervisor in the immediate aftermath of the injunction, I observed widespread anger and avowed defiance. Yet a small number of employees expressed philosophical agreement with Dwyer, pleased that the obsession with timber harvest might possibly be coming to an end.

Indeed, when Wendy Herrett became forest supervisor in 1990, she tried to refocus the Siuslaw's mission away from timber and toward other forest values, but she encountered intransigence from many employees who regarded her with deep suspicion, even hostility. Herrett seemed almost relieved that Judge Dwyer had imposed his decision on the Forest Service. Herrett sought to carefully navigate through this unstable environment, recognizing, inevitably, that a very different future lay in store.

The spotted-owl controversy emerged as a key environmental issue in the 1992 presidential election. I cannot recall another Forest Service or environmental issue that figured so prominently in a presidential race. Candidate Clinton visited Oregon, then a swing state, saying that he would fix the owl problem. Now President, making good on this campaign promise, Clinton convened a one-day forest conference in Portland, Oregon (as noted earlier), on April 2, 1993 with heavy regional news coverage. Almost all the President's cabinet along with Vice President Al Gore attended, listening all day long to sincere and desperate pleading from all sides that had a stake in the outcome.

The President noted in his opening remarks, "The worst thing we can do is nothing. As we begin this process, the most important thing we can do is to admit, all of us to each other, that there are no simple or easy answers. Let's confront problems, not people."

In the months following Clinton's Portland appearance, the leadership group of Siuslaw National Forest had engaged in a discussion of our resource management purposes for this landscape. I have never been involved in a more rancorous and passionate clash over resource ideology. Our capacity for unified leadership was clearly fractured; achieving consensus seemed impossible. Yet, I think this exercise helped the Siuslaw's leadership team prepare for the sweeping changes that resulted from the forest conference because we had already contemplated a dramatically different future.

In the "owl region" (western portions of WA, OR and northern CA), the planning effort to develop the owl solution yielded a draft NWFP in July 1993, an astoundingly swift, 90-day effort. The final NWFP, a sweeping new vision for federal forest management, was issued in April 1994.

Briefly, the NWFP accomplished two aims: it satisfied Dwyer's demand that vertebrate species populations remain viable (a legal requirement of the National Forest Management Act), and it also struck a new balance point between owl habitat protection and timber production by sharply reducing logging on federal lands inhabited by owls. The reductions took the harvest level down from about 9.4 million cubic meters per year to less than 2.5 million.

The NWFP was very complex, and radically different from the management plans it replaced. With my first reading, I was aghast. Many of the plan's foundational concepts were theoretical and untested. As a transformational forest management model, it placed an enormous burden on our field organization to make profound and swift changes to how we did business.

The Journey Begins: Implementation

I vividly recall announcing the NWFP decision to a large group of Forest Service and Bureau of Land Management employees at Corvallis's Majestic Theater. I began my remarks with a simple rhetorical question: "Do you believe this plan can work?"

I thought this was the central issue because it focused on personal will. The NWFP had been crafted by research scientists, unlike all the individual forest plans that had been developed by local forest managers. Most managers resented the idea that researchers had usurped their prerogatives to dictate how their forest should be managed. Managers also assumed the new plan would be an unwieldy, impractical, unworkable guide. These factors fomented skepticism. There seemed to be remarkably little commitment to make the NWFP work, or even to give it a chance.

However brilliant the NWFP might be, field personnel had to believe in it or it would not work. I suspected many, perhaps most, employees thought the NWFP flawed, deficient, and unworkable. I assumed the work of implementing the NWFP would be difficult, yes, but it merited my best effort. So I answered my own question: "Yes. I believe the plan can work."

In addition, just after the release of the NWFP, I delivered a speech to the public and agency employees, titled "Uncle, Thank You, Please." The speech sent a message to the public and agency employees that the NWFP openly admitted a need for change ("Uncle"), that we owed a debt to environmentalists for their passionate insistence on principles of sustainable stewardship ("Thank You"), and that we needed time and patience to perform up to new expectations ("Please").

How deep the hole we found ourselves in? The NWFP reduced Siuslaw annual timber harvest by 97%, far exceeding even my most severe prediction. This dramatic change held dire implications for the timber industry and our workforce, since timber harvest had been the lifeblood for the Siuslaw. This level of reduction would mean thousands of loggers, truckers, and millworkers would lose their jobs, as well as hundreds of our staff.

Moreover, few agency leaders outside the planning team itself had an opportunity to methodically consider the natural resource implications of the NWFP because of the secrecy surrounding the plan before its release. In general terms, Siuslaw staff could, given enough time, put the pieces together for how to comply with the NWFP. Bringing a distrustful, cynical public along with us was an entirely different matter.

Clearly, it seemed a losing proposition to continue to invest effort and large sums of money in traditional clear-cut harvests of mature timber, even at a vastly reduced pace. Some critics thought the Siuslaw targeted owl habitat for destruction, but it was more the case that the birds used virtually all the available mature forest habitat. If we cut big timber, we necessarily bumped into birds.

On top of that, we had to think about the dramatic reduction in wild fisheries over the past decades. Urgency demanded that we try to restore fish habitat on the Siuslaw's abundant streams.

The Forest Service has navigated its way through numerous controversies in the past century, but few have been as complex, layered, and consequential as the northern spotted owl issue. The NWFP rationale for drastic reductions in timber harvest was based on the fact that large-scale clear-cutting of old-growth forest profoundly affects fish and wildlife habitats. The convergence of owl, murrelet, and salmon habitats in the Oregon Coast's temperate rainforest coalesced to bring Siuslaw timber production to a virtual standstill.

I regarded the NWFP as an explicit admission that this incredibly productive landscape could not simultaneously maximize both wood products and wildlife. The forest was the womb that sustained this natural abundance. Thus, the NWFP made the hard choice for federal land. The remaining mature forest in the Coast Range would stay standing.

Building a New Boat

Economics was really the only motive for cutting mature timber. Most stands in the Coast Range originated in the mid- to late-1800s and could be characterized as being in the prime of life, since they often lived to be 500 years old. Biologically speaking, no need or urgency existed for logging mature timber.

Our tree plantations, however, were another matter. We knew that nearly 50,000 ha of young stands had grown up on sites that had been clear-cut starting back in the 1950s, emulating industry practices of clear-cut, remove snags, burn the site, plant seedlings, and spray herbicides. Many of these young stands were, or soon would be, of sufficient size to support commercial thinning.

These plantations were not natural in the same sense that coastal forests naturally regenerated themselves following the large, infrequent, severe fires that have swept through the Coast Range over centuries. I thought about it this way: when you cut and remove all the standing trees, then plant only one species (Douglas-fir) to densities that exceed 1000 trees per hectare, the dense packing of these trees ultimately exclude almost all other plant life. And that was the point—to grow Douglas-fir (because of its economic value) and eliminate the competition. The plantations had a destiny: clear-cut again at age 70 and start the process all over again.

So there was a legitimate concern that these tree plantations would not attain our desired mature-forest character evident in natural stands without further management. Having been created and managed solely for timber production, plantations had far too many trees, and they also lacked diversity. We decided to focus our available budget and resources on management of these young stands, but not for wood production. We thinned plantations, rather than clear-cut at age 70, to reorient them toward a new destiny as old-growth forest.

Our simplified strategy would allow the mature forests in the Coast Range to age and become old growth in time, without our intervention. Our management strategy would focus on the many young stands peppered throughout the landscape to improve the likelihood that they too would someday provide high-quality old growth (Fig. 1).

We knew our thinning strategy would also have significant financial consequences. The stumpage value (value of standing trees on the stump) of logging mature forests often approached 20,000 dollars per hectare in 1994 when the NWFP was issued. Thus, the value of standing timber on this relatively small forest easily exceeded \$10 billion. In contrast, thinning a young stand might yield only a few hundred dollars per hectare.

Politically speaking, many environmentalists familiar with the management and history of the Siuslaw remained skeptical and distrustful. They were pleased that the NWFP dramatically reduced logging and promised to save fish and wildlife, but reserved judgment on future steps to restore forest ecosystems. We desperately needed to create a credible scientific premise for our strategy, and decided to work closely with both Oregon State University and the agency's Pacific Northwest Research Station.

Fig. 1 Levi Beelart; thinning in young plantation to reorient to become eventual old-growth forest. Photo: Alan Honick.

Good Intentions and Good Fortune Meet

A research project, Coastal Oregon Productivity Enhancement (COPE), helped our progress significantly. COPE, a 10-year research partnership supported by money from government, industry, and interest groups, was housed at Oregon State University. As a COPE board member, I sensed we had a unique opportunity to do thinning research. Stu Johnston, a forester at Mapleton Ranger District, designed a study to evaluate three different levels of thinning on plantation sites that had more than 500 trees per hectare. The thinning study called for taking out most of the young trees, but leaving stands with 250, 150, and 75 trees per hectare, as well as establishing a control site where no thinning would occur.

We used a traditional commercial timber-sale process to achieve the treatments, awarding the contract to a high bidder. We conducted this study and several replicates to see which thinning treatments work best in encouraging a young stand of trees to grow into the old-growth forest characteristics that certain wildlife need for their habitat.

The COPE partnership conducted several field seminars in hopes of establishing that this unique management approach really could work in young forest stands. I vividly recall the tension when we first met with a pretty sizeable group on a wet day in early morning at the Mapleton Ranger Station before proceeding to the woods. For environmentalists, the rage of feeling ignored and abused for decades haunted the tours. For loggers whose bubble had burst, they begrudged their diminished role and being asked to come back to work as “partners” with the Forest Service under radically different rules. Slowly, incrementally, we gained credibility, building on the scientific rigor of our harvest trials and the evident sincerity of our “good intentions”. This was no ruse designed to just log our way out of the impasse. Within a period of about 2 years we had swayed doubters to at least give us a fair chance to continue our efforts at forest restoration. More specifically, forest thinning achieved one of three principal goals. The other two: significantly reduce the environmental footprint of the vast road network, and undertake targeted stream restorations. In combination, these three comprised our best assessment of what it would take to make measurable progress on the NWFP’s wildlife and fish goals.

As a result, we gained credibility with a variety of interest groups—federal regulatory agencies such as the US Fish and Wildlife Service and the National Marine Fisheries Service, state and federal forest managers, industry foresters, and environmental organizations. These stakeholders now united to assent to our 3-pronged restoration management framework, which could be seen as largely consistent with the NWFP.

The above describes what I consider an ad hoc, seat of the pants, informal approach to gaining traction, perhaps permission, on a new social contract with our “forest owners”—the amorphous public. The NWFP mandated several formal structures as well, such as interagency working groups, and a large 24-person resource council (a mix of agency officials and selected citizen representatives of notable interests; timber industry, environment, and such). I viewed these formal settings as essential, but not ultimately decisive in moving the needle related to the broad field of public sentiment and values. The informal approaches seemed more authentic and transactional, giving private citizens of all stripes a voice, and an opportunity for face-to-face dialogue and accountability.

Getting our story out through media contacts also helped immensely. For example, High Country News, a biweekly newspaper “for people who care about the West” requested permission to reprint the “Uncle, Thank You, Please” speech, and I gladly consented. HCN, well respected and widely read, offered a huge media footprint for people who cared about national forest issues. Scott Stouder, a logger turned environmental writer (featured on 60 Minutes with correspondent Ed Bradley), penned several investigatory articles in the Corvallis Gazette that helped local people keep up with changes afoot on the Siuslaw. Jeff Barnard, an AP reporter, repeatedly reported on key stories, particularly about salmon restoration. And the late Kathy Durbin, reporter for the Portland Oregonian and author of *Tree Huggers*, enthusiastically carried word of the “timber evolution” on the Siuslaw.

Revisiting the chicken and egg analogy, I am convinced that changing public sentiment from avowed opposition to positive support hinged on first creating a credible plan, and to then coalesce a variety of interests around the new vision and approach. If we had tried to ask citizen help to build from an empty tableau, I doubt we could have succeeded.

Why? Despair and confusion reigned thick and suffocating in the aftermath of the Dwyer decision. I could not conceive of appearing in public settings with no semblance of a road map and destination. The untested NWFP provided a general framework, but we needed to add layers of local specificity to lay out a credible way forward. It needn't be perfect, but it must signal a significantly different approach that addressed the crisis at hand.

Slowly, over a transition period that lasted about 3–4 years, we moved public perceptions of Siuslaw management from suspicion to curiosity, curiosity to acceptance, and acceptance to enthusiastic support. An important metric related to project appeals and litigation. When I arrived in 1991, every timber sale was aggressively opposed by numerous parties. Opposition fell to nearly zero, of course, as our logging approached a near dead stop. As we retooled our timber program to feature thinning young plantations and then accelerated, we held our breath to see if the old combat terms would return.

Remarkably, there has not been a single timber sale appeal or lawsuit since 1995. Siuslaw National Forest enjoys this singular distinction among all 154 national forests. I describe this phenomenon as literally unheard of in agency history. This outcome testifies to the salubrious benefits of restoring good will and trust, and the occasional triumph of human endeavors in overcoming past acrimony.

Thus, I'd say our good intentions met with good fortune, and we seized opportunities where found. Lest I leave the impression that the Forest Service alone achieved such successes, I note the numerous amazing citizens who stepped forward to make contributions large and small. It was as if the sight of an open field afforded them the opportunity to unleash their collective love of their public lands to help create a viable way forward.

Looking back over those tumultuous times, I can identify one pivotal event in 1994 that crystallized the moment our forest organization made the leap from the old to the new. Our leadership team was in a rather heated discussion about where to go with our timber program. Some were trying to persuade us to retain as much of our traditional clearcutting activity in mature forests as possible ("We're the Siuslaw! It's what we do!"), while others thought we should acknowledge that was a dead end, that it was time to pursue thinning. We needed a decision.

I had heard enough, and my guts told me to take a stand. I said, "We will no longer clear-cut mature timber on the Siuslaw." It seemed a bit like stepping into the abyss, but from that moment forward we would devote all our energy to thinning plantations. This was our future for as far as I could see; we had decades of this work before us. Today the Siuslaw is still at it, but with a wary eye toward that future year, estimated to be about 2030, when the work of thinning old plantations is done.

Pressing the Priority of Fish

Restoring streams to assist the recovery of depleted salmon formed an important bookend to our forest work. Merging more holistic terrestrial and aquatic environments yielded a more comprehensive product, and fit well with the Siuslaw because it is, more than any other national forest, a "timber and fish place." To have done one without the other would have been a significant injustice. And, as with our timber work, the social dimension of our aquatic work significantly improved the process and product.

During my first summer on the Siuslaw in 1992, I took a trip to Mapleton to visit an innovative fish-habitat project. I left my parked car and headed for the sound of workmen in Knowles Creek, which meets the highway from Eugene to the Coast a few miles east of Mapleton, where it joins the Siuslaw River. Mapleton's district ranger invited me out to look at the Knowles Creek Project, promising a look at some cutting-edge salmon restoration.

Knowles Creek runs only about 15 miles from beginning to end. The creek's drainage basin includes land owned by the Forest Service, the Bureau of Land Management, and Hancock Timber Resource Group, a spinoff of the insurance giant, whose timber holdings lay nearby. Like most coastal streams, Knowles Creek had a once-abundant fishery that had been damaged by serial assaults over the years.

Huge cedar stumps dotted the floodplain, evidence of the mighty trees that had once grown there. Numerous clear-cuts blanketed the hillsides above us. Sadly, Knowles Creek seemed typical of most coastal streams—pounded by logging, its fish largely gone, with little trace of naturalness.

It was late summer, with just a trickle of water moving. Huge logs, some as big as 3 m in diameter, lay strewn about ready to fabricate a logjam. Long, stinger-like drill bits pierced holes through the logs and also into sandstone bedrock. Then wire cables were inserted through the trees and epoxied into the sandstone to anchor the logs in place.

I met forest technician Lynn Hood, who enthusiastically explained how this logjam, and others like it, would slow the water and trap gravel to improve salmon habitat. I didn't see much water, and I sure didn't see any gravel.

I confess, it seemed a bit comical. Such big logs, so little water - a bit like the folly of Noah's Ark, unless you knew there was a flood coming.

Perhaps sensing my skepticism, Hood said I needed to come back during a winter storm, when Knowles Creek was galloping with about two meters of water. He was confident the logjam would hold tight and do its job.

I said, "What about the gravel? Where's the gravel?"

He pointed upstream. "Oh, it's up there. Trust me. It'll come." Hood smiled, but his conviction conveyed serious belief. I'm sorry, but I wanted to laugh.

The three-way collaboration involved the Forest Service (labor and money), Hancock (logs), and Pacific Rivers Council (the design and know-how of Charlie Dewberry, the Council's staff fisheries biologist). I was standing at one of about 15 artificial logjam

sites, each constructed in an effort to replicate natural conditions. Such logjams commonly occurred as a natural component of stream function when towering trees fell into the water.

Government foresters once required that timber companies remove these logs because they thought the logs obstructed salmon migration. Later, research showed that in situ wood in streams greatly improved salmon habitat. Now we were putting logs back.

Fast-forward a few years to an epic 1996 flood that dumped about 65 cm of rain into the Knowles Creek basin, hammering the vicinity. Dewberry revisited the area, his hopes high. If his design proved sound, the flood would use the logjams and further the work that human hands had started, dramatically improving salmon habitat.

Dewberry was pleased to see that almost all his structures had held. Huge, deep gravel bars lay neatly deposited upstream from where the logjams had slowed the floodwaters. I too have been back to Knowles Creek many times. I can scarcely believe it is the same place I first saw. On my first visit, Knowles Creek resembled a sandstone bowling alley, slicked to bedrock, devoid of gravel and wood. Today it looks natural, utterly transformed.

What's more, rigorous sampling of fish numbers reveals dramatic increases. Chinook (*Oncorhynchus tshawytscha*) and Coho salmon are now prospering where they once hung by a thread. Even Chum (*Oncorhynchus keta*) salmon, which had completely disappeared, now return.

This is a remarkable success story. Unfortunately, salmon populations have faded in literally thousands of other Knowles Creeks needing similar work. Given the saturation level of the problem, how does progress happen? One step at a time.

Another big step in our fisheries restoration effort occurred at Enchanted Valley. Located a few kilometers northeast of Florence, the aptly named valley is traversed by Bailey Creek, which empties into Mercer Lake and thence into Sutton Lake before threading its way a couple more kilometers under a new name (Sutton Creek) through low, open sand dunes into the Pacific Ocean. Enchanted Valley is much like, but smaller than, many of Oregon's mid-coastal valleys due to the area's geology. Mountain streams emerge into broad, flat valleys, then into freshwater lakes, before making a brief run to the ocean.

Dairy farmers found these valleys ideal for their herds. Farmers improved their pastures by literally moving these slow, meandering streams to the edge of the valley with dikes and ditches. Farmers filled in old creek channels and removed bankside trees. This agricultural "improvement"—usually subsidized by the US Department of Agriculture—ruined habitat for the resident salmon. Beautiful though it was, Enchanted Valley looked nothing like the way it did in 1900. As elsewhere, Bailey Creek's salmon suffered.

Coho salmon once thrived in these systems. Adults wildly spawned in the upper forested reaches of Bailey Creek, their eggs yielding new hatchlings that would grow to become smolts in the creek's lazy meanders and the lakes' depths before making the short run to the ocean. Salmon have a strong fidelity to particular streams. Adults almost unerringly return to the same stream where they were born. Consequently, once a fishery is lost, restoration can prove difficult since native fish do not often wander to repopulate neighboring streams. Numerous Coho populations, including the population in the Bailey Creek area, are now endangered.

Unlike Chinook salmon that hatch and return to saltwater in just a few months, Coho spend over a year in freshwater. Young smolts need to survive both the low water flows and high temperatures of summer and the heavy, roiling floods of winter. Life in a ditch spells trouble, but a natural creek is ideal.

Crack fisheries biologists on my staff spoke to me passionately about the opportunity to restore Enchanted Valley, describing Bailey Creek as almost perfect for restoration. The idea was to dig an artificially meandering channel in the middle of Enchanted Valley where Bailey Creek had once flowed, and then plug the ditch and return water to our "manufactured" creek. Reducing the gradient in this way would double the length of the creek and slow the water before it enters Mercer Lake. Importantly, such channel engineering allows the stream to leave its banks during high flows to reconnect with the flood plain. The last step is to plant shrubs and trees such as cedar and spruce to improve shading and help keep waters cold.

I grasped that this relatively cheap concept had a high probability of success. The State of Oregon volunteered to help finance the project. If it worked, the strategy could be replicated on numerous other coastal streams to create pockets of high-value Coho salmon habitat.

But once again, competing resource uses complicated what seemed at first to be a simple bonus for fish. The Rocky Mountain Elk Foundation had purchased Enchanted Valley in about 1985 and then brokered a deal transferring ownership to the Forest Service in return for assurances that the valley would be managed for elk (*Cervus elaphus*) winter range. The Siuslaw Rod and Gun Club played a prominent role in hyping this deal. The former cattle pasture became tremendous elk habitat, abetted by the Forest Service, which mowed the meadows every fall to keep the grass in a "juvenile" condition to enhance its palatability for elk. I can attest to the fact that elk loved it because I saw them on almost every visit. Hunters enjoyed having a big local elk herd that afforded high-quality hunting.

When we aired the idea of a fisheries restoration project in Enchanted Valley, controversy gathered like iron filings to a magnet.

Officers of the Siuslaw Rod and Gun Club let me know they viewed my ideas as a threat. How could the Forest Service—and more particularly I, myself—ever consider "ruining" perfectly good elk range for the benefit of fish? Hadn't the Forest Service acquired title to the valley by virtue of the Rocky Mountain Elk Foundation's generosity? Elk advocates strongly felt I violated the spirit of that deal. I also heard rumblings from local Forest Service staff that even they thought the proposal did not keep faith.

I saw things differently. Elk were not hurting in the Coast Range, but salmon were in deep trouble. Our actions would slightly diminish both the quantity and quality of elk habitat once the streamside trees grew to large size, but would not eliminate it. Changes would occur slowly, giving the elk herd time to adapt. If the fisheries project worked—and we thought it could, though we could not guarantee it—the benefits to salmon would be huge, and we would have a tested, viable technique that could be applied in many other places.

At the public meeting we held in Florence, citizens had plenty to say, mostly opposing the project. They had heard that even Forest Service opinions split between elk and salmon since many Forest Service employees were avid elk hunters. Not surprisingly, no consensus emerged.

I ultimately decided to do the Enchanted Valley project after careful consideration of dissenting views. The Rod and Gun Club appealed my decision, but, on review, the regional forester in Portland supported my decision. We pulled money together, issued contracts, and the dirt started to fly.

The transformation of Bailey Creek was rapid and dramatic. The new streambed emerged from the construction phase, and vegetation quickly healed the raw spots. The day came to cut the water loose into the new channel, an event welcomed with nervous anticipation. Bailey Creek performed like a perfect gentleman, the water easing into the channel and slowly sauntering toward Mercer Lake. The creek embraced its new course as if returning to the haunts of its youth.

Then the fish did their job. Salmon returned to spawn, and the new channel proved a happy home (Fig. 2).

It takes 3–4 years to complete the salmon cycle—smolts head for the ocean, mature, and return as adults to spawn. The first year those spawning adults returned to Bailey Creek, their numbers had increased by about 10-fold. And succeeding years have continued to strengthen the population. Bailey Creek is now a high-quality salmon stream—and the elk continue to graze in the valley.

After I left the Siuslaw in 1999, much bigger salmon restoration projects followed in several places, including Karnowski Creek and the Salmon River estuary, applying techniques from Knowles Creek and Enchanted Valley. Great things are happening. I occasionally think back to Knowles Creek and my opinion that little could be accomplished. I was so wrong.

Levering Salmon, Our Beloved Icon

Unlike the old-growth forest debate—with opponents lined up on both sides over whether big trees needed to stand or fall—salmon were much loved by all. Salmon represented the best of Oregon: wild, beautiful, romantic, hardy, and adventurous. And also in rapid decline. Siuslaw National Forest, with its dense network of salmon waters, estimated at 1.6 lineal kms per square km of forest, enjoyed a reputation as a “fish forest”; more so than any other outside of Alaska and British Columbia. If salmon were to enjoy meaningful recovery, the Siuslaw represented a potent opportunity. Public sentiment ran strong for recovery efforts, but did lack a crucial ingredient—funding. If a way could be found to finance stream restoration, we knew we had strong public support to build an aggressive program.

We benefitted from strong synergies that tied our successes in forest restoration to strengthen stream and fisheries funding. “Stewardship contracting” authorities made their way through Congress, built in part on Siuslaw achievements, enabling us to retain profits from our forest thinning program for discretionary local spending. In addition, Senator Ron Wyden (D, OR) authored a bill that authorized expenditure of federal monies on private land to benefit fisheries. These outcomes created a virtuous circle—non-controversial timber thinning achieved forest restoration while generating jobs and money, the money created

Fig. 2 Creating a new streambed, Fivemile-Bell Project near Florence OR. Photo: Justin Anderson USDA Forest Service.

opportunities for badly needed stream restoration projects, forest ecosystems and salmon fisheries both improved, and these outcomes deepened and strengthened public support and commitment to the Siuslaw's new business model.

The chicken and egg syndrome animated our approach to stream and salmon restoration, much as it did in navigating our approach to forest restoration. Our nascent approach to stream restoration achieved demonstrable results that informed discussions about how best to restore endangered salmon stocks. With sound techniques available to answer the "how," we still had to answer the question of "where" and "when."

The NWFP required that we develop watershed restoration plans, and these provided an anvil for us to hammer out consensus on best practices to achieve both forest and stream restoration. We chose to create watershed "councils" as the fora to process our deliberations. We also chose to keep our several councils very informal, intending to avoid onerous provisions of the Federal Advisory Committee Act. Importantly, formal committee structures tend to yield less effective and timely business transactions. Our *modus operandi* featured ad hoc structures and consensus decision-making. Forest Service staff experts would provide details on project proposals to interested parties in attendance—often nearby landowners, environmental group representatives, timber industry personnel, and private citizens. Project descriptions included location, cost and revenues, techniques, resource objectives, known issues, potential cooperators, and so on. Facilitated discussion allowed participants to speak their views, then worked through "red flags," desired modifications, and positives, to ultimately yield consensus on sequencing selected projects, and an understanding of anticipated benefits and consequences.

Improving the plight of salmon served as a strong unifying force to allow foes (remember that long-term, bitter controversy had heretofore dominated dialogue) to take the first tentative steps to respectfully talk to one another and negotiate in good faith. The Forest Service took on the role of honest broker, being unfailingly honest, transparent, well-behaved, and resolute that something would get done. We could not afford to waste people's time and effort. Applicable laws and regulations bounded decision space, but, beyond that, we made every effort to accommodate consensus decisions.

Slowly but perceptibly, progress emerged. People found they could work together and bridge disagreements. It is trite, but true nonetheless, that opponents actually agreed on more things than they once thought possible. Trust and hope began to grow. It took years to achieve strong, cohesive working groups. But these groups developed a deep pride of accomplishment at working through what had once been insurmountable hurdles to agree on broadly supported priorities and projects to restore their public lands. I thought it quite remarkable that a national forest that had been in total disarray could so quickly be "resurrected" through the effective teamwork of government officials and private citizens, working in concert to address persistent resource issues while overcoming deep enmity among participants.

I describe the approach as "letting the owners back in the room," and the Forest Service commonly uses such collaborative approaches now. Yet, while collaboration brings many positive forces to decision-making, I offer a few words of caution.

First, government staff, operating as meeting facilitators and brokers, plays a key role in setting the tone and gently refereeing disputes. The virtues of respect, trust, honesty, balance, and lack of guile are crucial. If other participants sense that cards are withheld or not revealed, dialogue is poisoned, usually irreparably. Favoritism is also toxic, as is any hint that outcomes are foreordained. But exemplary behavior is rewarded with optimal outcomes.

The agency must also be clear on how applicable laws and regulations bound the decision space so that participants don't waste time on creating solutions that cannot be implemented. If people have a clear understanding where the walls are and how big the room is, reasonable decisions will follow.

A subtle danger of collaboration is settling for the least offensive solution, in the misguided belief that this constitutes success. When dealing with a landscape in need of restoration, people should be encouraged to develop optimal, not minimal, solutions. Groups need to grapple with the question "what's *really* going on?" and craft solutions that answer the question effectively.

Lastly, government officials need to trust in outcomes that represent the group's best effort. Substituting individual judgment for a group's hard won consensus surely destroys trust.

A Last Word

In hindsight, I am still astonished that the Forest Service sold more timber in 1989 than ever in its history. Environmental groups escalated their opposition throughout the 1970s and 1980s, and the Forest Service response was to increase timber harvest. It is true that powerful political interests influenced the Forest Service timber agenda. Long-tenured western senators favored a robust timber program, and a lengthy series of Republican presidents who were traditionally pro-commerce—Nixon, Ford, Reagan, and Bush—combined to weight the scales in favor of industry, but I did not see much evidence of principled push-back from a compliant Forest Service.

The crisis visited on the Pacific Northwest via the northern spotted owl seems almost inevitable in hindsight. Remarkably, Siuslaw National Forest - a landscape caught in a powerful vortex of opposing forces—was transformed by bureaucrats and citizens working in concert to create a hopeful future. The Siuslaw pushes forward with strong public support and little controversy. The environmental community now endorses the Siuslaw's embrace of forest restoration principles and pleads, "Why can't all national forests be managed this way?"

Managers of Siuslaw National Forest chose to approach the future by focusing on managing for properly functioning ecosystems, rather than timber production, spurred on by a new forest plan that envisioned a radically different policy for public forests. Now 25 years old, the Northwest Forest Plan's track record has been marked by the tug and pull of successive administration's

political priorities. The federal agencies in charge of public lands, notably Forest Service and Bureau of Land Management, have been less than heroic, wobbly even, in their willingness to adhere to the tenets of the Plan in the face of political pressures. Significant threats remain to be addressed as climate change worsens and barred owls (*Strix varia*) have overwhelmed spotted owls throughout much of their range. Politicians renew the push for more logging on federal lands with seemingly little care for or attention given to the circumstances that, painfully neglected, created one of the great environmental crises of our time. Policy makers may forget, but these magnificent forests bear scars. This is no time to ignore history.

Abstract

Canada, like many nations around the world, is struggling to find solutions to both climate change impacts and biodiversity loss. Given the enormity of these problems, opportunities to align government policy responses are highly appealing. In Canada's Boreal Forest biome there is a compelling case that conservation designations of large landscapes can help slow biodiversity losses, including of iconic threatened species like boreal woodland caribou (*Rangifer tarandus caribou*), while increasing the likelihood that massive stores of carbon in those landscapes will remain there. The Boreal Forest biome of Canada is estimated to hold a minimum of 208 billion tons of carbon. Only 11% of the total carbon stored in soils and vegetation in Canada is now within existing protected areas. At least 69 billion tons of carbon are stored in unprotected intact landscapes that support woodland caribou.

Introduction to Boreal Forest and Its Carbon Stocks

North America's Boreal Forest biome ([Fig. 1](#)) is one of the most ecologically intact on the planet with the footprint of human industrial activity ([Fig. 2](#)) estimated at between 17% and 26% while the area protected is between 8% and 13% ([Lee and Cheng, 2010](#); [Andrew et al., 2014](#); [Carlson et al., 2015](#)). The largest proportion (88%) of the North American Boreal Forest biome lies within the national boundaries of Canada ([Brandt, 2009](#)).

The biome is known to hold an immense amount of carbon in storage ([Fig. 3](#)), the result of thousands of years of accumulation of sequestered carbon in plant materials that was then prevented from decomposing by cold temperatures and acidic ground conditions. The total amount of carbon within the biome held in storage, mostly in soils and peat and under permafrost has been estimated to be a minimum of 206 Gt ([Carlson et al., 2009, 2010](#)).

Even this amount is considered likely a gross underestimate as only a relatively small proportion of the 6.27 million km² biome have been adequately sampled and the extent of deep peat deposits, especially those under permafrost, is poorly understood ([Schindler and Lee, 2010](#)). To put this in global perspective, the total amount of carbon in Canada's Boreal Forest region is equivalent to a minimum of 71 years of current annual emissions from China, the world's largest polluting nation and 111 years of current annual emissions from the United States, the world's second largest polluter and over 1000 years of current annual emissions from Canada.

The density of carbon across the Boreal Forest biome is estimated to be approximately twice that of the density of carbon in tropical forests because of the exceptionally long residence time of biological carbon within Boreal Forest ecosystems ([Carlson et al., 2009](#)). This is in contrast with the rapid decomposition of carbon sequestered in warm, tropical forest ecosystems. Tropical forest ecosystems sequester more carbon annually than do Boreal Forest ecosystems but much of that carbon is returned to the atmosphere quite quickly and does not build up in the soils. Boreal forest ecosystems sequester less carbon annually than do tropical forest ecosystems but the carbon has remained in the soils, peat, and under permafrost for thousands of years, building up a much larger storage bank of carbon overall.

Peatland systems including bogs, fens, and forested wetlands within the biome are particularly carbon rich ([Wells et al., 2010](#)). One of the largest wetland and peatland systems in the world is the Hudson Bay-James Bay Lowlands, an immense 373,700 km² area extending from Manitoba, across northern Ontario to western Quebec ([Abraham and Keddy, 2005](#); [Warner and Asada, 2006](#)). These wetlands are estimated to hold 30–35 billion tonnes of carbon ([Riley, 2011](#); [Humphreys et al., 2014](#); [Packalen et al., 2016](#)), making up nearly 20% of all the carbon stored in Canada's Boreal Forest biome.

Fig. 1 The extent of the North American Boreal Forest biome as delineated by Brandt (2009).

Fig. 2 The Canadian portion of the Boreal Forest biome with intact areas that have very little human industrial footprint shown in *green*. More than 70% is still considered intact, making it one of the last, very large ecological areas on the planet.

Fig. 3 Soil organic carbon density across Canada's Boreal Forest biome. Particularly carbon rich areas occur in the Hudson Bay-James Bay Lowlands of Ontario, Manitoba, and Quebec, and in the Mackenzie Valley of the Northwest Territories.

Potential Impacts to Stored Boreal Carbon Stocks

Industrial development and the resulting supporting infrastructure can impose major changes to the landscapes of the Boreal Forest region (Far North Science Advisory Panel, 2010). These changes can include disruptions of hydrological levels, flows, and cycles any of which can have profound implications for releasing organic carbon stored in peat and soils, and releasing highly impactful greenhouse gases, especially methane. Industrial development can also cause changes that increase permafrost thaw in some areas, again allowing the release of carbon stores that have been in place for thousands of years.

Just as in the field of medicine, the approach to taking care of the carbon stores of the Boreal Forest biome should be to "do no harm." Such a precautionary approach would lead to the conclusion that along with advancing global policies to decrease atmospheric carbon levels, decision makers should advocate for maintaining as much of the Boreal Forest as possible free from human industrial activities that increase the chances that its carbon stores will be lost to the atmosphere (Carlson et al., 2009).

Today only about 10% of the carbon stores of Canada's Boreal Forest lie within the boundaries of protected areas (Fig. 4). However, at least two-thirds of the carbon within Canada's Boreal Forest is within still intact forest blocks (Fig. 4). That means that it is still possible to establish very large protected areas that contain within their boundaries much of these vast stores of carbon so that carbon will be protected from loss caused or exacerbated by resource extraction activities.

Boreal Biome Landscapes Are also Biodiversity Rich

The same boreal forest ecosystems that sequester carbon and hold it in storage below ground, support globally significant biodiversity, largely above ground (Bradshaw et al., 2009). Those globally significant features include:

- Some of the highest densities and largest individual numbers of northern tree species anywhere in the world (Crowther et al., 2015);

Fig. 4 Overlap between soil organic carbon stores and protected areas across Canada's Boreal Forest region.

- Billions of nesting birds, most of which migrate south to populate temperate and tropical biomes across the Western Hemisphere during the northern winter season (Blancher and Wells, 2005; Wells, 2007; Wells and Blancher, 2011);
- Large and wide-ranging populations of large mammal species including herbivores like caribou (*Rangifer tarandus*)—including boreal woodland, mountain, Newfoundland, and tundra forms—wood bison (*Bison bison athabasca*), and moose (*Alces alces*), and large predators like gray wolves (*Canis lupus*), grizzly bears (*Ursus arctos*), black bears (*Ursus americanus*), and polar bears (*Ursus maritimus*), and wolverines (*Gulo gulo*) (Laliberte and Ripple, 2004; Hummel and Ray, 2008; Wells et al., 2013);
- East-west ice-sheet species divergences and ice age refugia lineages across a broad array of taxa, yielding surprising and little-known levels of biodiversity (Wells et al., 2013).

History of Boreal Woodland Caribou in Canada

The boreal woodland caribou was once a widespread species occurring as far south as the northern U.S. (Fig. 5). An advancing frontier of development in New England, the Maritimes, and Quebec led to a steady disappearance of boreal woodland caribou from its southern extent. The species disappeared from Vermont by 1840, Wisconsin by 1850, the St. Lawrence Valley of Quebec by the mid-1800s, Prince Edward Island by 1873, New Hampshire by 1881, Maine by 1910, Nova Scotia by 1912, Cape Breton by 1925, Michigan by 1931, and Minnesota by 1942 (Ray, 2010). The decline and northward range retraction have continued so that woodland caribou are gone from 60% of their original range in Alberta, 50% of their original range in Ontario, and 40% of their original range in British Columbia (Hummel and Ray, 2008). In Ontario the species range has retracted north at a rate of 34 km per decade from 1880 to 1990 (Vors et al., 2007; Schaefer, 2003). The boreal woodland caribou was listed as Threatened under Canada's Species at Risk Act in 2000 (International Boreal Conservation Science Panel, 2011).

Fig. 5 Current (dark green) and former (red) range of the Boreal Woodland Caribou.

Boreal woodland caribou have survived and adapted under the often-harsh conditions of the northern latitudes through a strategy of using vast landscapes to maintain distance from key predators and obtain food (Hummel and Ray, 2008; Schaefer, 2008). For example, in perhaps the most critical time of the year for caribou populations—the spring/summer calving period—females become solitary and move to islands, peatlands, and lake shore areas where they and their newborn calf will have the least likelihood of being found and preyed upon by wolves, bears, or other predators (Schaefer, 2008). This strategy of being able to shift around the landscape as conditions change and to space themselves out from predators, each other, and other ungulates requires large areas of the species preferred habitat mosaic of 50–100 year old mature spruce or pine forest, large peatlands, lakes, and rivers (International Boreal Conservation Science Panel, 2011).

Boreal woodland caribou avoid broadleaf and mixed-wood forests, as well as cut-over forest, roads, powerlines, and other forms of industrial human impacts while wolves and their targeted prey of moose, deer, and smaller mammals occur in higher numbers in such habitat. As a boreal woodland caribou herd's range becomes converted to non-caribou habitat, not only is there less habitat for them to use and more predators to try to avoid, but there is less ability for the species to avoid predators and find preferred habitat (Schaefer, 2008; International Boreal Conservation Science Panel, 2011). In fact, the number of calves that are born and survive shows a constant decrease as the proportion of the landscape impacted by human industrial activities increases (Environment Canada, 2008, 2011). A general rule of thumb indicated by this research is that a herd has a high probability of local extinction once more than about 38% of their range has been converted either through human-caused changes to the landscape or fires or a combination of the two. In fact, maintaining a low density boreal woodland caribou herd (not necessarily a density that would allow the herd to withstand hunting pressure or climate change impacts) is thought to require single unfragmented habitat blocks at least 10,000–20,000 km² though only six protected areas of this size have been established within the species range (International Boreal Conservation Science Panel, 2011).

Boreal woodland caribou have now been lost from half of their original range and this loss is likely permanent as there are no known cases of woodland caribou reoccupying portions of their range where they have been extirpated despite a number of sophisticated and expensive attempts at reintroductions (Schaefer, 2008; Festa-Blanchet et al., 2011). This loss is clearly the result of human-caused changes to the landscape working in combination with resulting changes in associated predator-prey communities that negatively

impact woodland caribou. If this rate of range loss were to continue, the species would be lost from Ontario within 100 years. If the same rate were applied to other provinces, the species would be lost from Alberta and Manitoba within 100 years, and Saskatchewan and Quebec within 200 years. Unfortunately, the expectation is that the rate of loss will likely increase because of climate change and the degradation of the species' ability to rebound and recolonize. In fact, [Environment Canada \(2008\)](#) estimated that only 17 of the total of 57 surviving boreal woodland caribou herds or population units had a greater than 50% probability of being self-sustaining ([Fig. 6](#)). These 17 units encompassed approximately 25% of the entire boreal woodland caribou's remaining range. Environment Canada's 2008 assessment also estimated that in 46 (80%) of the 57 boreal woodland caribou herds or population units, maintaining or developing the potential for that population to be self-sustaining would require a halt in further industrial disturbance.

Preventing further losses and ensuring long-term viable and abundant populations of boreal woodland caribou in Canada will require setting aside very large proportions of boreal forest habitat from large-scale industrial disturbance ([International Boreal Conservation Campaign, 2011](#)). Populations should be maintained and increased to levels that also allow for harvest for use by Indigenous peoples for sustenance and maintenance of cultural values ([UPCART, 2017](#)).

Protecting the Boreal Landscape to Mitigate the Effects of Climate Change on Boreal Biodiversity

The effects of climate change to the world's biota are, sadly, already well underway. The northward movement of thousands of organisms retreating from hotter and harsher condition as a result of the increase in global temperature is now very well documented from numerous studies ([Root et al., 2003](#); [Parmesan and Yohe, 2003](#); [La Sorte and Thompson, 2007](#); [Zuckerberg et al., 2009](#); [Langham et al., 2015](#)). One of the most important global strategies for allowing species to adapt and survive climate change impacts is through the maintenance of the last remaining blocks of intact, primary forest worldwide ([Carlson et al., 2009](#); [International Boreal Conservation Campaign, 2013](#)). Boreal forest regions are particularly important because they are the last reservoirs of habitat for species forced northward by intensely warm and hostile ecological conditions in temperate regions of the globe ([Wells et al., 2018](#)).

Fig. 6 Survival probability of each of 57 Boreal Woodland Caribou herds or population units as described by Environment Canada (2008). Only those herds shown in *green* are thought to have a high chance of persistence through maintenance of the current habitat conditions.

Other species are in need of immediate conservation action to prevent their current rapid declines and stabilize their populations enough to ensure that they have a chance of maintaining resiliency in the face of climate change. Species like boreal woodland caribou that have already lost nearly half of their historic range and are listed under Canada's Species at Risk Act as Threatened, are likely to disappear from vast portions of Canada without rapid protection of their remaining intact habitats.

Boreal Woodland Caribou Ranges and Carbon Stores Show Wide Overlap

Mapping the overlap of boreal woodland caribou range in Canada with best available soil organic carbon data (Tarnocai et al., 2009) shows broad overlap with the largest area of high-density carbon stocks within the still-intact portions of woodland caribou ranges at the national scale (Fig. 7). The total estimated stock of soil organic carbon summed across the entire ranges of all herds of woodland caribou including the already impacted portions of their ranges is 129 Gt, amounting to more than half of all the carbon stocks estimated for the entire Canadian Boreal Forest biome.

Portions of boreal woodland caribou ranges that are free from any industrial disturbance (including logging and major roads) hold 69 billion tons of carbon in storage within the soils, peat and permafrost beneath the habitat with 7.7% (10Gt) estimated to be encompassed within the boundaries of protected areas. This is more than a third of the total stock of carbon estimated to be held within the soils, peat, permafrost and forest vegetation of Canada's Boreal Forest biome.

Clearly, protecting boreal woodland caribou habitat would also have great benefits for protecting carbon stores and vice versa. There are countless other examples of the potential co-benefits of establishment of very large protected areas for protecting carbon stores as well as for the maintenance of biodiversity today and under the future challenges imposed by climate change. Incentives should be developed to support stewardship of terrestrial carbon stores that conserve large intact landscapes that support woodland caribou populations. Such incentives could include financial support to support Indigenous protected and conserved area development (ICE, 2018) and management tied to voluntary or government-mandated carbon-reducing policy mechanisms and markets.

Fig. 7 Overlap of soil organic carbon stores and caribou ranges in Canada.

Abstract

A great values clash unfolded in the late 1990's as the US Forest Service sought to resolve a long-festering environmental conflict over the fate of roadless public lands, comprised of 25 million hectares largely in the American West and Alaska; fully 2% of the entire land area of the United States. Conservationists had bitterly opposed the continued logging of these natural areas while the Forest Service relied on unlogged roadless lands to supply a beleaguered timber industry. The clash was particularly noteworthy in the Pacific Northwest, home of most of the remaining intact forests, following immediately on the heels of the spotted owl crisis that was resolved in favor of conservation interests to severely limit further clearcutting of old-growth forests. The Roadless Area Conservation Rule (2001) again resolved a consequential issue in favor of conservation interests by limiting commercial logging and roadbuilding in roadless areas. Lengthy litigation followed, culminating in 2013 when the Tenth Circuit Court of Appeals supported the Rule. A notable but unexpected outcome of this dramatic policy shift is a significant increase in stored forest carbon following logging reductions. Such carbon gains team with other "free" environmental services like clean water and air, and high quality wildlife and fish habitat to illustrate important non-commercial forest values.

The Untold Story of Roadless Area Protection

The legitimacy and relevancy of the US Forest Service stood at a crossroad: one road led down a familiar, increasingly arduous and costly path—that of pursuing logging and roadbuilding into untouched reaches of public forest; the other road led in a new direction—turning away from a utilitarian mindset to protection of 23 million hectares of natural lands (2% of all US lands), as yet untouched by commercial logging.

The answer emerged in due time; the Roadless Area Conservation Rule took effect on January 6, 2001 in one of President Clinton's last official acts.

What follows is a glimpse into the unseen bureaucratic battle to craft this regulation, as seen from my perspective as Deputy Chief of the Forest Service when I played a key role in bringing the regulation to fruition.

The Context

I assumed my duties as deputy chief in May 1999, and I had come prepared with my short list of priorities representing what I hoped would engage my best efforts to move the agency's national forests in a new direction.

I soon learned that the Forest Service Chief, Mike Dombeck, also had a short list that subsumed mine. I knew of his focus on watershed restoration, such as salmon recovery and protecting forest headwaters that supplied much of America's domestic waters. In fact, my interest and accomplishments in this area had everything to do with my being selected as deputy chief.

A major surprise lay in my path. Within days of my arrival, Dombeck informed me that the Forest Service would undertake promulgation of a regulation to protect roadless areas. Although I had a hint of this proposal from an earlier moratorium on road construction within inventoried roadless areas, the audacity and sweep of this proposal stunned me.

For decades, roadless areas had been the source, or pool of lands, from which Congress designated wilderness. Roadless lands also served as the best source of new timber because they generally had little or no prior logging. Roadless areas enjoyed no official status until the Forest Service undertook a national Roadless Area Review and Evaluation, begun in 1967 and completed in 1972. The RARE review, as it was called, recommended that 5 million hectares be set aside for wilderness. However, the accompanying environmental impact statement was challenged in court and judged to be deficient.

USDA's assistant secretary Rupert Cutler, a former executive with The Wilderness Society, initiated a subsequent Roadless Area Review and Evaluation (RARE II) during the Carter presidency in 1977, seeking to improve on the original study. RARE II recommended 6 million hectares for wilderness and another 10.8 million for further study.

Given this heightened interest, subsequent Forest Service logging and road-construction activities in roadless areas were often stopped by environmental lawsuits. The environmental community attached great importance to protecting the wildness of roadless areas, and they regarded the Forest Service as a threat to protecting roadless-area values.

This values conflict echoed the lengthy battles over cutting old-growth forests. Forest Service dogma called for logging to convert old forest to “healthy” stands of young, vibrant trees. Yet the agency’s own research increasingly revealed that old-growth forests contained incredible diversity and complexity and served vital ecosystem functions. Far from being worthless, old growth held astounding value if one looked beyond mere timber products. The notorious spotted owl (*Strix occidentalis caurina*) controversy that dominated environmental politics in the Pacific Northwest in the late 1980’s had been the point of the spear in halting the systematic elimination of old-growth forests.

Similarly, roadless areas had long been regarded by the Forest Service as merely the next place one goes to log more trees. Even so, in 2000, after nearly 100 years of Forest Service management, there still remained about 23 million hectares of inventoried roadless areas—equivalent to an area the size of Wyoming. Congress had already created about 14.5 million hectares of wilderness. Thus, in aggregate, about half of the 78 million total hectares of national forest remained undeveloped.

Wilderness areas were predominantly high-elevation lands. Roadless areas, in contrast, occupied much more of the niche of mid-elevation lands that tended to be more heavily forested. The timber industry, as well as many people in Forest Service leadership, continued to view roadless-area protection as antithetical to multiple-use mandates. The Forest Service seldom championed the wilderness cause, and could even be said to resist it.

For example, in 1984, after a crippling recession had hurt companies with Forest Service timber contracts, Oregon’s Democrat Senator Mark Hatfield steered a bill through Congress that traded wilderness protection for a “release” of some roadless areas for immediate timber harvest. I recall, fresh upon arriving on the Siuslaw National Forest in 1992, looking at a road leading right into the bulls-eye of what had been one of the Siuslaw’s few remaining large roadless areas near Hebo, Oregon. When built, the road (which accessed several 1985-era clear-cuts) permanently nullified the area’s unmanaged, untrammelled character.

These roads were legal, thanks to Hatfield’s legislation. However, the “release” language did not require that roadless lands be compromised by logging and road construction. The swift action taken by the Forest Service eloquently symbolized the agency’s operational values. Protect roadless areas? Not if there were logs to be had. Furthermore, acting swiftly to compromise the area’s roadless character eliminated the nuisance factor, making future management less complex.

Roadless-area protection and timber production had been engaged in a slow-motion collision for at least 20 years. You’ve seen bighorn rams size each other up in slow-motion? There will be a crash! Yet, it seemed clear to me that the Forest Service controlled both variables (protection and production) and could have engineered a durable solution. However, the Forest Service made itself—quite intentionally—the greatest threat to roadless areas. When Chief Dombeck proposed that the Forest Service develop a regulation for permanent protection of roadless areas, agency traditionalists felt downright insulted.

But Chris Wood, Dombeck’s policy advisor, said that, in opting to protect roadless areas, “The Forest Service is becoming relevant again.” I won’t forget that remark. The sharp contrast between insulting and relevant made me ponder. I took Wood to mean that roadless areas were a huge issue to a vast constituency of environmentalists who viewed the Forest Service as an abuser rather than a protector of roadless areas and public lands in general. I thought this perception should have greatly alarmed agency leaders, but it didn’t seem to.

Agency Dinosaurs?

The fissures that appeared after Dombeck’s proposal revealed the agency as something less than one big happy family. Gloria Flora, Humboldt-Toiyabe National Forest supervisor in Nevada, made a rather public offhand remark about “dinosaurs” in Forest Service leadership who needed to retire. This outraged many forest supervisors who demanded that Chief Dombeck disavow her remarks.

Dombeck called me on the phone. “Could you come see me right away?” I took the back stairs to his office, which was just above mine. He asked me to read a letter he’d just received from Mike Lunn, Oregon’s Siskiyou National Forest supervisor. Dombeck told me the letter had been electronically copied to “almost everybody” in the Forest Service. He asked what I thought he should do.

The letter was a direct, personal appeal to the chief outside the normal chain of command—except that it spoke to agency culture, not land management. Mike Lunn took umbrage at Flora’s statement, and he gave the chief a hard-edged testimonial as to how the “dinosaurs,” including himself, had built and sustained a great organization. The letter was a forceful defense of the old guard, tinged with defiance, contempt, and disrespect. The letter was also honest. Lunn was clearly calling Dombeck out as to how the chief felt about dinosaurs—like Lunn himself. The chief had an upcoming interview with *Time* magazine and now expected questions on this brouhaha.

Lunn’s letter demanded an immediate response, and I suggested that Dombeck first call Lunn to thank him for his letter, for having the guts to tell him what he was thinking. I told him, don’t argue; just be open, and listen if he’s got more to say. Then reassure him that you value agency leaders and all they do and have done for the Forest Service. I said that Lunn needs to hear that the chief of the Forest Service doesn’t consider him and his colleagues to be dinosaurs. Then, I said, write him a brief response, reiterating these few points. Address the reply to Lunn only. If Lunn wants to mail it around, let him. Don’t escalate, but don’t be dismissive.

Dombeck did this. In a few days, many thousands of agency employees had seen Lunn's letter as it spread via email. In these days before blogging, hundreds of commentators piled on via email using a "reply all" command, so that the effect multiplied geometrically. Folks generally piled on adulation for Lunn's "telling it like it is!" I recall almost no recognition of Dombeck's response.

Emboldened, Lunn wrote yet another letter, basically doubling down and getting in more licks. Dombeck took the high road—no response this time. But the Lunn letters boldly revealed in our field leadership a lack of trust in Dombeck and feelings of betrayal. Hard stuff.

Ticking Clock

Hermann Gucinski, a Forest Service research scientist in Corvallis OR, was lead author of *Forest Roads: A Synthesis of Scientific Information*. This comprehensive report described both the benefits and the adverse consequences of roads and road use. Other research demonstrated that roadless lands are the best landscapes in terms of water quality, fish and wildlife populations, endangered species, and healthy forests. These lands are also bulwarks against invasive species because they have an essentially robust natural character that road construction tends to degrade.

The Forest Service now found itself caught in a powerful vortex, a result of failing at the critical task of solving prominent problems. Until now, I had been at the field level striving to facilitate logging to meet agency targets (as noted, much of the timber supply came from roadless areas) while being generally aware that the agency flailed in court defending such actions. This had been going on for some two decades, and attested that the former approach failed to resolve the issue—figuratively kicking the can down the road year after year, time and money both wasted. Effectively serving the public demanded that the Forest Service craft a progressive policy to deal decisively with roadless areas and resolve the issue.

I found it remarkable that politicians in the Clinton administration, notably Chief of Staff John Podesta and Council on Environmental Quality Chair George Frampton, trusted the Forest Service for the undertaking. One overwhelming, simple reason accounted for that: Chief Mike Dombeck. The chief often lamented that the Forest Service had become extremely defensive and apprehensive trying to defend its logging legacy. "It's going to be a lot more fun playing offense," he'd say, grinning broadly. He believed roadless-area protection would be very popular and likely to win the admiration and restore the trust of a cynical environmental community. News media often editorialized about how Forest Service leadership drifted weakly in the face of public antipathy, seeming to have run off the rails. Dombeck relished the idea of sitting down in front of editorial boards from the *New York Times*, *Washington Post*, and *Los Angeles Times* to discuss the opportunity to contend for roadless-area protection.

Several difficult realities confronted the Forest Service in resolving one of the most sweeping and controversial issues of the past several decades. Completing a regulation governing 23 million hectares would affect virtually every national forest from coast to coast. Opposition would quickly mount, particularly from the conservative western states that held the vast majority of roadless lands. As anticipated, but sadly, some of the most intense opposition would come from within the Forest Service.

And there was the clock. This was summer 1999. A presidential election loomed in November 2000. Political reality required that a regulation be completed before President Clinton left office. There were two reasons: first, the Democrat Clinton wanted credit for a key environmental accomplishment; second, we needed to sustain momentum, because we knew the election of a Republican would stop the effort dead. We submitted a project calendar with all the requisite time periods—60 days for this, 90 days for that—indicating we could complete the project by mid-December 2000, after the election and before the January inauguration of a new president. An achievable assignment, but one with no margin for error or delay.

But we had no task team organized for the roadless issue. We were figuratively entering unknown territory without a map. Dombeck approached me with the challenge to find someone to lead the roadless effort—one of the most significant Forest Service challenges in its history. The job needed to be done well, it had to be done on time, and failure was not an option. I thought to myself, "I've got just the person in mind."

Bill Sexton, my old boss on the San Juan National Forest, was now laboring in a staff position in DC. He had openly voiced his hopes for a promotion to become a prestigious regional forester. I mentally connected the dots—take on the roadless issue, get it done, and the Forest Service will owe Bill Sexton a favor. Name your dream job. It's yours! It didn't hurt that Sexton was capable of doing just about anything he put his mind to.

I spoke with Sexton and made the pitch. His response was matter-of-fact: "Not interested. There will be a Republican president in 2000. Anyone who touches this roadless thing will be dead meat."

I bristled. I had not expected such a blunt assessment; so much for nuance. In that moment, any thought I had of cajoling or persuading Sexton into leading the roadless team vaporized because we needed a leader who believed in the work without reservations. I then called Sharon Heywood, Shasta-Trinity forest supervisor in California. Not interested. I put out an SOS call to all regional foresters. I needed help, urgently. Regional foresters acted stumped. Perhaps they agreed with Bill Sexton's sentiments and didn't wish to sacrifice anyone to political suicide?

Finally, Brad Powell, regional forester for California, called to say he had someone in mind: "Scott Conroy on the Modoc."

I felt a deep anxiety. I had met and knew most of the 120-plus forest supervisors, but I'd never even heard of Scott Conroy. And few considered the Modoc National Forest (office in Alturas, in the far northeast corner of California) to be an impressive locale. It seemed we were nearing the dregs of our candidate pool, when I was seeking the crème de la crème. I reminded Powell that this was the most important thing the agency had done in decades. Can we trust this issue to Conroy? A lot hangs on the outcome.

Powell told me that he thought Conroy might be just what we needed. He was competent, very disciplined, and could be relied on to get things done.

I reported to Dombeck on my efforts to find a person to lead the roadless effort. I noted my disappointment that the regional foresters couldn't help us identify any top-flight candidates. I also mentioned the Bill Sexton episode. Dombeck noted that at least Sexton was honest and agreed that we didn't want him: "We need a believer."

I got the nod to vet Conroy. Frankly, I had few options left. Maybe I needed to trust in Conroy's competence simply because the Forest Service always tried to pick capable people for forest supervisor jobs. That, coupled with Powell's endorsement, encouraged me. Then everyone I spoke to enthusiastically supported Conroy. Now it was time to speak to him myself.

Conroy immediately impressed me with his deep desire to help the Forest Service accomplish this historic task. He knew it would be tough sledding, but he liked a challenge. My concerns that he might be unequal to the task, or worse, oblivious to the difficulties, waned. Importantly, he believed roadless areas needed protection and wanted to be a part of it.

I said there were no guarantees, but if we could pull this off, he'd likely get a good promotion. Was he interested in greater responsibilities? Yes!

We had our team leader. I called Brad Powell to thank him for his help, though I still harbored doubts that we could succeed.

Making Hay

In the next few months, bureaucratic wheels turned quickly. We published a Notice of Intent in the Federal Register to prepare an Environmental Impact Statement and regulations to achieve roadless-area protection. Scott Conroy recruited eager, enthusiastic specialists of all kinds for his task team. We swung into our public involvement effort, the most ambitious in agency history. We conducted roadless-issue meetings for all 125 national forests, as well as many formal public hearings. We cooperated with other agencies such as BLM, Park Service, and Department of Justice. It was an incredibly hectic full-on press.

Since most roadless areas were in the West, timber industry groups and western Republican governors whipped up strong headwinds to blow the effort off course or, better yet, onto the rocks (Fig. 1). Chris Wood and I traveled to Salt Lake City to meet with several governors' representatives, all suspicious of the political overtones of the effort. The meeting was hostile and tense.

"Why now?" was the trenchant question. Everybody recognized roadless protection as a potent issue. We all knew the implications of the coming election as the political clock ticked on. Wood gamely explained that roadless issues had grown and festered for

Fig. 1 Distribution of roadless areas throughout the United States, with heaviest concentrations in western states and Alaska. Source: USDA Forest Service.

decades, fostering doubt, legal uncertainty, and needless expense. It served no one's interest to leave this important issue undressed. While Wood spoke, I got the feeling the gang mentally searched for the best way to stop us.

Wood and I had anticipated that some of them would ask for cooperating agency status, which would essentially make them partners in our effort, a figurative bone thrown their way. But this would effectively give these prospective partners power to sabotage the project. And they did ask, but we fended them off, saying that it would be impractical and unworkable, since so many states were involved. If we made one state a cooperating agency, we'd have to do the same for all. We vowed to keep the states' governors informed throughout, but we were firm that only federal agencies would be cooperating agencies.

Pandemonium ensued. When Montana's representative pressed us hard on this issue, we asked why he counted this privilege as essential. He said, "We want to delay the process so that you can't finish the job before Clinton leaves office." They would take their chances from there on a hoped-for Republican White House pulling the plug on roadless-area protection.

Silently, I gave him high marks for honesty. After overcoming my shock at his brazen position, I stated that this was not a valid rationale for a cooperator. We left with a firm "No. You'll be hearing from us. Thanks for coming."

Other aspects of developing the rule flowed well. As the Forest Service held hundreds of public meetings, the volume of comment on the rule was massive, unprecedented. With Pew Environment Group funding a big advocacy campaign, the Forest Service received well over 1 million comments on our draft proposal. We had no precedent for processing and analyzing this volume of feedback, yet a task team heroically accomplished this as well. The trajectory of our effort held pretty tightly to the project calendar. We were still optimistic about concluding our work in December 2000.

Alaska, as usual, required special handling. Among the 23 ha of roadless areas, Alaska's two national forests, the Tongass and Chugach, contained about 5 million hectares—fully 20%. Of the two, the Tongass National Forest in southeast Alaska (remarkably, a bit larger than West Virginia) has long been a political hotbed. With 11,000 miles of coast and 57,000 miles of streams, the spectacular Tongass is regarded by the environmental community as the crown jewel of all national forests. For its part, Alaska's congressional delegation historically regarded the Tongass as its parochial domain, passing out logging and mining favors to local residents and businesses. The Forest Service is caught in a pincer-like grip between environmental constituents and powerful politicians.

With nearly 4 million hectares of Tongass roadless area distributed throughout this vast 7-million-acre archipelago of coastal rainforest (along with 3 million hectares of designated wilderness and National Monument lands), the destiny of these roadless areas loomed as a huge unresolved issue. Rather than propose any particular preference in the draft Environmental Impact Statement, we chose to defer the ultimate fate of Alaska's roadless lands to the final decision phase and simply invited public comments about the issue.

Mike Dombeck asked my opinion about the best future for Alaska's roadless lands. Having never visited Alaska, I told Dombeck I lacked a good enough feel for Alaska to provide a sensible answer. Thus, in August 2000, I made an unforgettable trip to Alaska with the chief's question in mind.

I immersed myself in the splendors of Alaska, accompanied throughout by Forest Service officials, primarily Rick Cables, the regional forester. Alaska's enormous spaces, raw exuberance, and uniqueness left me deeply touched, almost speechless. All Americans should visit Alaska to let it speak to their souls.

Over a period of several days, Cables conveyed that Alaska's roadless lands needed to remain available to local citizens for subsistence, commerce, and the basics of community sustainability. Uniquely, almost all of southeast Alaska is national forest land, meaning Forest Service management and decisions govern every aspect of life for Alaskans. In brief, Cables believed the lands' greatest value lay in utility, not protection.

Upon my return to Washington, I met with Dombeck to discuss my view on protecting Alaska's roadless lands. I described as best I could the nature and complexity of Alaska's roadless issue, ultimately siding with Cables's view that comprehensive, extensive roadless protection was unnecessary. Dombeck's face remained deadpan and he said little beyond thanking me. The few questions he did ask seemed rhetorical. I left with a sense that he disagreed with and was disappointed in my position.

Ultimately, the Forest Service decided to apply restrictions on further logging and road building to all of Alaska's roadless lands. Dombeck explained the key decision criteria to me like this: "Alaska's roadless lands are the best we have. We need to protect the best."

His logic had a simple, profound elegance that perhaps I failed to appreciate at the time. There exists much nuance between the poles of protection and wise use of lands. The choice is almost never clear, and claims are often mutually exclusive. I found the arguments of both sides compelling. Alaskans do rely heavily on the Tongass for the basics of life. Ecologically, the Tongass is of global significance. That makes the Tongass roadless area situation a wicked dilemma and why I found it difficult to see this clearly at a crucial moment.

In early December, we published the final Environmental Impact Statement and the proposed Roadless Area Conservation Rule, with a 30-day waiting period before it became effective. George Frampton, chairman of the Council on Environmental Quality (CEQ) and the president's leading spokesman on environmental matters, chaired a briefing for all federal agencies interested in the roadless proposal.

The Department of Energy was one very interested agency. The Roadless Rule proposed to ban any more road building in connection with oil and gas leases, beyond roads that existed or those needed for current leases only. North Dakota's Little Missouri National Grassland held a potentially huge but relatively undeveloped gas field for which restrictions on road building would make development, if not impossible, much more costly and difficult.

A contingent of several Department of Energy officials made an impressive (and late) entrance. The one woman among them wore a bright red dress, exuding power.

The leasing issue quickly arose. Frampton laid out the premise of the regulation on leasing. The Department of Energy quickly weighed in using strong, unequivocal terms: this must change. Frampton countered that the prohibition on new roads was a well-considered element of the rule. Acknowledging an explicit trade-off, Frampton said it was needed to protect roadless lands from the probability of more “dry holes” that would achieve little except to ruin more precious roadless lands.

The DOE contingent ratcheted up the argument, saying it would not accept any outcome other than making a last-minute change to the regulation.

It seemed clear to me that this conflict would have to come before White House Chief of Staff John Podesta and maybe President Clinton himself. And sure enough, in the next few days the regulation was rewritten to exempt any renewed lease from road-building restrictions. DOE won the argument, while CEQ gained some solace by retaining restrictions for all future leases. Prophetically, the lands in question later became a centerpiece of resurgent oil and gas industry in North Dakota as federal energy policy fostered a friendly environment for fracking.

The final rule was published in the Federal Register on January 6, 2001. Two weeks before George W. Bush assumed the presidency, William Jefferson Clinton, clad in a black overcoat, proudly made a presidential announcement at the National Arboretum, with gently falling snow dappling his shoulders. It seemed a perfect ending to a strenuous but deeply satisfying effort.

I reflected on all that happened in the past 18 months. I’d been given the opportunity to help resolve a festering conflict by fashioning regulatory protection for roadless areas. Nearing the end of my career, I had helped fashion a sweeping, bold policy for the environment. The same Forest Service that had been aggressively logging and building a vast network of roads into natural landscapes wheeled about-face to strive for durable protection—but protection from what? From the Forest Service itself.

Upon Reflection

It may prove useful to consider changes set in motion by roadless area protection that I consider to be profound: (1) a major victory for the environmental community alongside cessation of old-growth forest logging; (2) a new perspective forced on the Forest Service to consider more protective management options for roadless lands; and (3) forest carbon sequestration getting its due as vitally important to managing climate change factors.

Let’s look at these changes through the lens of public land forestry in the vast Douglas fir (*Pseudotsuga menziesii*) forests of the Pacific Northwest where sharp contrasts exist between activity pre- and post-roadless protection since 2002.

The Pacific Northwest is home to much America’s most intact forests, and these forests are also the most economically valuable. But any consideration of values must also include biological and even spiritual factors. The northern spotted owl controversy epitomized the clash of monetary and other at-odds values in a highly visible and protracted fight ultimately decided in the courts in 1991. Winners and losers became evident, but the courts offered no path forward. The Clinton administration resolved the legal morass by crafting a political pathway in 1994, in which commercial timber interests decisively lost ground following a decisive swing toward more ecologically conscientious policies. The environmental community declared victory but remained wary of backsliding (which did occur during the succeeding Bush administration).

Logging in the Pacific Northwest relied heavily on roadless lands for further old-growth harvests, even after the Clinton Plan reduced quotas from 9.6 million m³ to 2.4 million per year. Thus, roadless area protection increased the bind by restricting commercial logging and road building. Whereas the spotted owl victory achieved a notable regional win for the environmental community, roadless protection achieved a monumental national victory. Remarkably, every legal challenge to the Roadless Conservation Rule failed in spite of the Bush administration electing to provide no defense. Environmental organizations intervened as friends of the court to mount a successful multi-pronged 12-year defense that ultimately vindicated the legitimacy of roadless protection.

These two remarkable environmental victories grew out of the Clinton administration’s sensitivity to values other than commercial timber, and have largely endured due to changing public values and legal requirements. Yet insistent voices for the primacy of commerce on public lands remain effective, if wounded. As I write, the Trump administration prods the Forest Service via executive order to increase logging by 30% in hopes of reducing risk of catastrophic fire, such as Paradise CA experienced in late 2018. Personally, I doubt that logging one’s way out of the current climate-driven fire conundrum will work.

The second point reflects, until now at least, the durability of roadless protection. Rather than logging and roadbuilding being the defining characteristics of Forest Service roadless policy, rules now legally require the agency to restrict commercial logging and new road construction in favor of protecting roadless area attributes and values like clean water and naturalness. This change clashes with a residue of traditionalist culture in the Forest Service, and has proven difficult to embrace.

The Bush administration fashioned a “work-around” whereby any state could petition to create unique roadless policies, though at considerable time and expense. Idaho and Colorado did so shortly after the original 2001 rule took effect, and Alaska and Utah began additional petition efforts in 2018–19. Forest Service officials quite eagerly made requisite cooperative gestures. In each case, the respective Governor chose to surgically loosen certain protections in the 2001 rule (such as for the ski industry in CO, and phosphate mining in ID), but the bulk of protections remain in effect currently. Thus, in spite of a few erosions, significant protections remain in effect to guide Forest Service actions in 23 million hectares of roadless areas, about 30% of the entire national forest land base.

The regressive move back to localized solutions unique to individual states reflects a long-standing reluctance to deal with national issues at a national, agency-wide level (e.g., clearcut logging, old-growth forest protection). The 2001 Roadless

Conservation Rule sought to resolve a decades-old national scale issue at a national level, after repeated local efforts had failed to pass legal muster, nor provide consistency. The environmental community exhibited enthusiastic support for a comprehensive policy that restricted commercial logging and roadbuilding—one governing all national forests—while critics (including many Forest Service officials) groused at loss of local control.

Furthermore, some Western states, notably Utah, remain fixed on converting federal lands to state ownership—a solution that would moot federal roadless area protection. The notion that federal lands should be given to states is deeply rooted in the premise that the federal government's ownership of public lands in western states is illegitimate. This notion is in direct contravention of the Property Clause of the US Constitution (Article 4), whereby the federal government reserved ownership of public lands unto itself when granting statehood to western states, and has been settled law based on Supreme Court rulings for over 100 years. The notorious 2016 occupation of the Malheur National Wildlife Refuge by “The Bundy Brothers” symbolized this fanciful movement.

Thus, although protection of roadless lands has strong and tested legal underpinnings, the political arena remains somewhat fraught.

Thirdly, the importance of forests in mitigating climate change dynamics has emerged relatively recently, both globally as well as in the Pacific Northwest region where Douglas-fir forests are among Earth's most prodigious carbon stores. Yet the relationship between climate change and forest carbon went largely ignored as recently as 2000 by those of us formulating the Roadless Area Conservation Rule. Remarkable new data from Forest Service inventories of forest carbon tells an interesting tale.

Using Oregon as an example, we see that the capacity of forest lands to store carbon increases when timber harvest declines (Fig. 2). Recall that the Northwest Forest Plan (1994) reduced federal timber harvest from 9.6 million m³ per year to 2.4 million. That plan, in combination with restrictions on commercial timber sales in roadless areas, resulted in significant increases in storage of forest carbon between 1996 and 2012 (see Figs. 2 and 3). The annual rate of acquired carbon on national forests increased from 13 million to 34 million metric tons of CO₂ between 1996 and 2012. In fact, in the short time period 1990 to present, Oregon's federal forest lands have shifted from being a net source of carbon to being a very large sink today. This contrasts with private industrial forest lands that have reduced carbon stores in the same period, largely due to continued heavy logging.

Total national forest timber harvests have plunged from a high of about 26 million m³ per year to the current level of about 10 - million. Extrapolating from the example of Oregon, carbon stores on national forests increased as logging decreased. If carbon were

Fig. 2 Amount of forest lands in Oregon. Source: USDA Forest Service.

Fig. 3 Changes in forest carbon 1996–2012. Source: USDA Forest Service.

to be monetized at rates considered by the Office of Management and Budget, its value would greatly exceed that of wood products. This is not to say that logging on public lands should be eliminated. But the legacy of important conservation measures like the Roadless Area Conservation Rule has been to increase forest-based carbon significantly, even though this may have been an unintended consequence. In light of the urgency of climate change, forest carbon should be an important decision criterion in weighing the relative merits of carbon sequestration versus logging in federal forest policy discussions.

In conclusion, I believe my long Forest Service career gives me legitimacy to suggest that many agency officials remain unenthusiastic about the obligation to protect, rather than log, roadless lands. Time, research, and insight have demonstrated the long-term benefits associated with conserving roadless area character and values. The Roadless Area Conservation Rule remains among the most controversial policy initiatives in Forest Service history, and also among the most environmentally consequential. The federal government chose not to defend the Rule in court, yet it prevailed against numerous challenges due to dedicated defense by environmental groups. The Bush administration tried to scuttle the Rule but failed. Once again, the Trump administration seeks to water it down in Alaska and Utah. My hope has been that as time rolls on, the wisdom of protecting roadless values would become more apparent, obvious even. In sum, the roadless rule stands as a landmark national legacy and an important example of global opportunities available for other nations if we are going to slow down climate change.

Abstract

We present a status assessment of the Hawaiian islands dry forests, including the current status, stressors, and future viability. Dry forests generally have relatively low rainfall and are found on the leeward sides of the islands in lowland or in montane-subalpine zones. Historically, dry forests were located on all of the main Hawaiian islands and currently they are still found there. However, the quality of these forests is largely composed of a mix of native/nonnative vegetation. In addition to the native lowland and montane-subalpine dry forests that characterized dry forests historically, introduced dry forests and tree plantations are now classified as dry forests. Our assessment of dry forest viability, defined as the likelihood of persistence over the long term, is based on the conservation biology concepts of representation, redundancy, and resiliency. The main stressors to dry forests are invasive ungulates, plants, other herbivores, wildfires; drought; and agriculture and human development. Ongoing conservation efforts help to protect remnant patches of dry forests but this depends largely on combined efforts of various stakeholders. We developed four plausible future scenarios, each differing in levels of natural resource management, to evaluate the status of dry forests into the foreseeable future. Two of the scenarios, which are based on no change in conservation actions (Scenario One; status quo) and a slight increase in conservation actions (Scenario Two) have the highest likelihood of occurring in the foreseeable future while the other two, which are based on a slight to moderate

decrease in conservation actions (Scenario Three) and a moderate to large increase in conservation actions (Scenario Four) do not. Scenario Three would severely degrade and fragment native dry forest and result in reduced resiliency, redundancy, and representation. In Scenario Four, the substantial improvements in restoration of native dry forests would result in increased resiliency, redundancy, and representation.

Introduction

The Hawaiian archipelago is the most isolated landmass in the world separated by >3700 km from California. The archipelago consists of an expansive chain of islands located almost in the center of the Pacific Ocean, formed by the northwest movement of the Pacific tectonic plate over a volcanic hotspot where magma rises through the earth's mantle until it erupts through the seafloor. These islands range from small atolls in the northwest of the archipelago, to high volcanic islands in the southeast. As the islands increase in age they are carried northwest on the continental plate away from the hotspot. Currently located above the most active area of the hotspot, the island of Hawai'i is the youngest island in the chain and is still experiencing frequent, geologically-recent volcanic activity.

Climate in the Hawaiian archipelago is characterized by mild and equable temperatures year-round, low to moderate humidity, persistence of northeasterly trade winds, remarkable differences in rainfall within short distances, and infrequent hurricanes and severe storms (Wagner et al., 1999). Most areas in the Hawaiian archipelago experience only two seasons. Warmer and drier "summer" weather occurs between about May and September and slightly cooler and wetter "winter" weather occurs between about October and April (Wagner et al., 1999). The steep and rugged mountains of Hawai'i significantly influence its weather and climate.

The Hawaiian archipelago has an abundant range of biomes due to extreme variations in elevation, wind, rain, topography, substrate, and hydrology. The archipelago's remote location in the vast Pacific Ocean contributes to its physical geography. Each island and atoll has unique physical and biological features. We provide an overview of the dry forest in the Hawaiian archipelago and describe the ecological factors that have influenced the dry forest biome over time and into the future. A thorough introduction of the Hawaiian Islands can be found in the chapter by Harrington in this work.

Description

Defining Dry Forest Characteristics

Here we use the definition of a forest as a plant community characterized by vegetation with >25% tree cover (a woody perennial that usually has a single trunk) (Gagne and Cuddihy, 1999). Dry forests in Hawai'i typically have this woody overstory, and an understory which can be shrubby and/or herbaceous.

Dry forests in Hawai'i generally are located on the leeward sides of the islands in lowland or in montane-subalpine zones (Gagne and Cuddihy, 1999). These zones are differentiated by elevation and climate that primarily dictate which species can exist in them (Gagne and Cuddihy, 1999), and are described further in their respective subtype descriptions in the **Pre-human Condition** and **Current Condition** sections.

There are many ways to classify plant communities such as using elevation, moisture, and physiognomy. For example, Gagne and Cuddihy (1999) defined dry plant communities based on a moisture regime of 1200 mm of annual rainfall. Thus, we defined and characterized the dry forests of Hawai'i using two existing geospatial datasets (Amidon, 2018a,b). The 2014 LANDFIRE data was used to represent the current vegetation types of the main eight Hawaiian islands (LANDFIRE, 2011, 2014; Rollins, 2009). LANDFIRE data layer identified 40 land cover/vegetation types on the main Hawaiian islands. For the dry forest this included four categories: lowland dry forest, montane-subalpine dry forest and woodland, introduced dry forest, and tree plantation (introduced); which are described as subforest type in the **Current Condition** section. The moisture zone maps (Price and Jacobi, 2012), created by Price et al. (2012) of the main Hawaiian islands were used to define the dry regions on each island for the introduced dry forest and tree plantations only. Dry regions are a combination of the arid (areas that have a moisture availability index (MAI) value less than -689 mm), very dry (areas that have an MAI value between -389 and -689 mm), and moderately dry zones (areas that have an MAI value between 0 and -389 mm) as identified by Price et al. (2012). Estimated MAI values statewide were calculated using maps of estimated median annual precipitation and potential evapotranspiration values (Price et al., 2012). Therefore, the introduced dry forest and tree plantations are identified as having an estimated annual rainfall ranging between 10 to <160 cm, and rainfall is highly variable by elevation (Price et al., 2012).

Dry Forests occur on all of the main Hawaiian islands from 0 to 2900 m (sea level to 9500 ft) in elevation. Annual rainfall ranges between 30 and 200 cm (12 and 79 in) in lowland dry forest and montane-subalpine dry forest and woodland (LANDFIRE, 2016).

Geology

Substrates are highly variable but are generally well-drained, sandy loam soils derived from volcanic ash or cinder and weathered 'a'a or pāhoehoe basaltic lava for the lowland dry forest (LANDFIRE, 2016). The substrate conditions found within the montane-subalpine dry forest range from cinder, well-drained, loam soils derived from volcanic ash, and weathered 'a'a or pāhoehoe basaltic lava with little soil development (Gagne and Cuddihy, 1999).

Physical/life history components

Natural recruitment in the dry forest is driven by numerous factors including disturbance from fires, drought, hurricanes, volcanism, storms, pathogens, diseases, and invertebrate pests. It can also be influenced by rainfall, light, and nutrient availability.

Water availability in the dry forests is dependent on rainfall and elevation. In the lowland dry forests, rainfall occurs mainly in the winter (Gagne and Cuddihy, 1999). Whereas, in the montane-subalpine dry forest, drought conditions occur during the summer (Gagne and Cuddihy, 1999). Rainfall in the dry, leeward sides of the Hawaiian islands most commonly occur as a result of frontal storm systems that are distributed over a large area and are broad; and convective storm cells, which are localized to a particular area and are small (Cordell and Sandquist, 2008). The sporadic appearance of rainfall during drought periods from convective storms, although small and for the most part do not account substantially to annual primary productivity in dry grasslands and shrublands, are important in the maintenance and existence of woody plants (Cordell and Sandquist, 2008).

Fire can act as a primary driver for change in dry forests. Most native species in Hawai'i are not specifically fire adapted (Smith and Tunison, 1992), however, may respond favorably after disturbance if environmental conditions are optimal. Fire can reset the successional clock in this ecotype by removing a substantial amount of plants. Some seeds will survive and be able to germinate following the fire, however, others rely on dispersal from other sources such as the wind or animals.

Vegetation composition and vegetation structure

Vegetation composition and structure is defined by an open to dense tree layer ranging from 3 to 18 m (10 to 59 ft. tall (LANDFIRE, 2016). The dominant species of dry forests in Hawai'i are found in these species-rich families: Malvaceae (14 sp.), Rubiaceae (12 sp.), Rutaceae (9 sp.), Euphorbiaceae (8 sp.), and Fabaceae (7 sp.) (Pau et al., 2009). The most species-rich genera are *Melicope*, *Chrysodracon* (formerly known as *Pleomele*), *Psychotria*, and *Wikstroemia*, each containing six species (Pau et al., 2009).

Endemism in the tree species of the dry forests of Hawai'i are unusually high with 90% of all species endemic, 10% indigenous (native nonendemic), and 37% are single-island endemics (Pau et al., 2009). Most trees in the dry forests are evergreen (97%) and only four species are deciduous (tree shedding its leaves annually) (Pau et al., 2009).

Biodiversity

The biodiversity in native dry forests is high when compared to other native ecotypes in the Hawaiian islands (Gagne and Cuddihy, 1999; Cabin et al., 2000). The diverse native dry forests support many native bird and invertebrate species. Historically, native birds included large flightless geese and ducks (family Anatidae) and frugivores such as crows (family Corvidae) and thrushes (family Turdidae) (Chimera and Drake, 2011). Native frugivores aided in the processing of fruit or pulp removal of native plants and contributed to seed dispersal and germination (Chimera and Drake, 2011). Native birds and invertebrates also assisted in pollination within the dry forests resulting in increased reproduction and genetic diversity. Seabirds provided important nutrients from the marine environment such as nitrogen and phosphorus to the dry forests which are essential to vegetation recovery and health (Young and VanderWerf, 2016; Fukami et al., 2006; VanderWerf et al., 2014).

Pre-Human Condition

Dry Forest Subtypes

Before the arrival of humans, dry forest was represented by two forest subtypes: lowland dry forest and montane-subalpine dry forest (see Table 1 for a description).

Vegetation composition and vegetation structure of dry forest

In general, the pre-human dry forests in Hawai'i were comprised of 109 tree species in 29 families, with 90% of all species endemic, 10% indigenous, and 37% being single island endemics—with the greatest number of single island endemics located on Kaua'i and the island of Hawai'i (Pau et al., 2009). It is important to clarify, that this high diversity of species only takes into account the species composition found in the canopy layer of dry forests. The understory may have contained plants that commonly describe the dry grassland and shrubland ecotype such as *Heteropogon contortus* (pili) or *Dodonaea viscosa* ('a'ali'i). Additional information on the diversity of the species located in the chapter on Hawai'i dry grasslands and shrublands in this work.

Physical/life history components of dry forest

The historical fire regime in Hawai'i was characterized by infrequent, low severity fires, as few natural ignition sources existed (Cuddihy and Stone, 1990; Smith and Tunison, 1992). Prior to human colonization, fuel was sparse in dry plant communities and native vegetation had a low flammability (Smith and Tunison, 1992) and could not carry fire effectively before the introduction of nonnative grasses. Although fires were infrequent, Vogl (1969), in Cuddihy and Stone, 1990) proposed that naturally occurring fires may have been important in the development of some of the original Hawaiian flora, adding to the species richness of ecotypes, including the dry forests. The primary ignition sources were volcanism and lightning (Baker et al., 2009). In addition, lava flows as a result of volcanism can cover areas of forest and reduce their size.

Table 1 Prehuman conditions and current conditions of the dry forest subtypes of the Hawaiian islands.

Dry forest subtypes	Precipitation ^a (cm)	Elevation ^a (m)	Pre-human condition		Current condition	
			Characteristic plants ^b	Extent/range	Characteristic plants ^{a,b}	Extent/range ^{b,c,d,e}
Lowland Native Dry Forest	50–200	> 1000	<i>Alphitonia ponderosa</i> (kauila), <i>Bobea sandwicensis</i> ('ahakea), <i>Chrysodracon hawaiiensis</i> (hala pepe), <i>Colubrina oppositifolia</i> (kauila), <i>Diospyros sandwicensis</i> (lama), <i>Erythrina sandwicensis</i> (wiliwili), <i>Metrosideros polymorpha</i> ('ōhi'a), <i>Mezoneuron kavaense</i> (uhiuhi), <i>Myoporum sandwicense</i> (naio), <i>Myrsine lanaiensis</i> (kōlea), <i>Nestegis sandwicensis</i> (olopua), <i>Nothocestrum breviflorum</i> ('aiea), <i>Planchonella sandwicensis</i> ('āla'a), <i>Polyscias sandwicensis</i> ('ohe makai), <i>Psydrax odorata</i> (alahe'e), <i>Rauvolfia sandwicensis</i> (hao), <i>Santalum</i> spp. ('ilihi), <i>Sapindus oahuensis</i> (āulu, lonomea), <i>Sideroxylon polynesianum</i> (keahi), <i>Sophora chrysophylla</i> (māmane), and <i>Xylosma hawaiiense</i> (maua)	All of the main Hawaiian islands; across southwest and northeast Kaua'i, the entire island of Ni'ihau, the southern Ko'olau and Wai'anae mountains and a portion of the northern Ko'olau and Wai'anae mountains of O'ahu, parts of north, southeast, and western Moloka'i, the lowlands of the entire islands of Lāna'i and Kaho'olawe, the leeward slopes and central area of Maui, and the leeward slopes, parts of the southeast and northern portion of the island of Hawai'i (see Figs. 1–4)	'ōhi'a, lama, kauila, wiliwili, <i>Acacia koa</i> (koaia), <i>Gardenia brighamii</i> (nānū), <i>Hibiscadelphus</i> spp. (hau kuahiwi), <i>Kokia</i> spp., keahi, <i>Polyscias sandwicensis</i> ('ohe), <i>Achyranthes</i> spp., <i>Nototrichium</i> spp., 'a'ali'i, <i>Leptecophylla tameiameia</i> (pūkiawe), <i>Doryopteris decipiens</i> ('iwa'iwa), <i>Pellaea ternifolia</i> (laukahi)	All the main Hawaiian islands. However, areas consisting of predominantly native species are now rare and are best represented on the leeward sides of the islands
Montane-Subalpine Native Dry Forest	Between 30 and 120	Between 1000 and 2900	<i>Acacia koa</i> (koa), <i>Euphorbia celastroides</i> var. <i>lorifolia</i> ('akoko), <i>Euphorbia olowaluana</i> ('akoko), <i>Melicope hawaiiensis</i> (alani), 'ōhi'a, naio, kōlea, olopua, 'aiea, and māmane	Maui and the island of Hawai'i (see Figs. 1–4)	'ōhi'a, māmane, naio, koa, <i>Euphorbia celastroides</i> ('akoko), <i>Euphorbia olowaluana</i> ('akoko)	Maui and the island of Hawai'i. Best developed in the saddle region between mountains on the island of Hawai'i, with rich native plant communities. The range has decreased since pre-human conditions (see Figs. 1–4) primarily due to the expanding range of introduced dry forest and dry shrublands and grasslands

Table 1 Prehuman conditions and current conditions of the dry forest subtypes of the Hawaiian islands.—cont'd

Dry forest subtypes	Precipitation ^a (cm)	Elevation ^a (m)	Pre-human condition		Current condition	
			Characteristic plants ^b	Extent/range	Characteristic plants ^{a,b}	Extent/range ^{b,c,d,e}
Introduced Dry Forest	Generally between 50 and 200	Generally below 1000 m, but occasionally higher elevations	N/A	N/A	<i>Prosopis pallida</i> (kiawe), <i>Lantana camara</i> (lantana), <i>Schinus terebinthifolius</i> (Christmas berry), <i>Leucaena leucocephala</i> (koa haole), <i>Pennisetum setaceum</i> (fountain grass), <i>Andropogon virginicus</i> (broomsedge), <i>Schizachyrium condensatum</i> (beardgrass), <i>Cenchrus ciliaris</i> (buffelgrass), <i>Megathyrsus maximus</i> (guinea grass)	On the leeward sides of all the main Hawaiian Islands
Managed Tree Plantations	Various	Various	N/A	N/A	<i>Corymbia</i> spp. (gum tree), <i>Pinus</i> spp. (pine), horticultural or agricultural trees (coffee, fruit, nut orchards), <i>Casuarina</i> spp. (ironwood), <i>Paraserianthes</i> spp. (albizia), <i>Fraxinus</i> spp. (tropical ash), <i>Grevillea</i> spp. (spider flower)	Managed tree plantations are found on Kaua'i, O'ahu, Moloka'i, Maui, and the island of Hawai'i

Dry Forests Viability of Prehuman Conditions

The Hawaiian dry forest viability depends on maintaining multiple and distributed populations (redundancy) of sufficient quality and size (resiliency) with species richness and genetic range (representation) to survive across their ecological environment over time.

Historically, dry forests in Hawai'i covered large areas (Figs. 1–4) and were comprised of a wide range of species and diversity (see above). This high quality and large size would have helped dry forests tolerate natural, annual variations in the environment and recover from periodic disturbances (i.e., floods, minor fires, etc.). Should a period disturbance have occurred, the seed source had a large enough range and diversity of species to allow the dry forest to recover, thus making it resilient.

Both lowland and montane-subalpine dry forests were historically distributed and had wide ranges across all of the main Hawaiian islands (Figs. 1–4). This redundancy made dry forests less susceptible to catastrophic events such as an occasional hurricane or volcanic eruption. In the case of lava flows, these were localized events affecting only some populations of dry forests across the landscape. The distribution of dry forest in multiple units across the landscape and across the islands provided redundancy, which provided the ability to withstand events only affecting smaller areas of dry forests on individual or a few islands (e.g., single volcanic eruptions or hurricanes affecting multiple islands).

Habitat status assessment methods—Hawai'i, current condition summaries. Technical report from United States Fish and Wildlife Service, Pacific Islands Fish and Wildlife Office, Honolulu, HI, pp. 439.

The high diversity of tree species within dry forests (see above) is part of the high representation (the ability to adapt to changing environmental conditions and is measured by the variation across the landscape) found in this ecotype (Rock, 1913). Prior to human arrival, all plants, animals, and invertebrates arrived in Hawai'i by accident or by drift. Because of this isolation, species

Fig. 2 Map of historical and current extent of dry forest in Islands of Kaua'i and Nii'hau. Word from Reeves, M. K., and Amidon, F. (2018). were able to fill empty niches not already occupied by other species that lead to speciation (adaptive radiation) and a high rate of endemism; 90% for dry forests (Pau et al., 2009). As described, this endemism and diversity existed across the pre-human dry forest subtypes, thus leading to high representation.

Current Condition

Dry Forest Subtypes

While dry forests were represented by two subtypes before the arrival of humans, it can now be further subdivided to include not only the lowland and montane-subalpine native dry forest, but also introduced dry forests and tree plantations. Introduced dry forests are characterized by being dominated by introduced vegetation, but does not refer to tree plantations. Tree plantations are a forest type that was created by humans. A short description of each prehuman and current dry forest subtypes follows in Table 1.

Current Dry Forest Extent/Range

Tropical dry forests of the Hawaiian islands are ranked as the most threatened tropical forest ecosystem worldwide (Miles et al., 2006). Charles N. Forbes of the Bernice P. Bishop Museum, and the distinguished Joseph Rock of the then College of Hawai'i (now the University of Hawai'i at Mānoa) were the first botanists to characterize the flora of the Hawaiian islands in 1908–20 (Wester, 1992) and 1910, respectively (Rock, 1913). Rock (1913) noted the dry forests of Kahikinui District on Haleakalā, Maui, and Pu'uwa'awa'a in the district of north Kona on the island of Hawai'i, as the richest botanical regions in the islands. These lowland dry and mesic forests once were considered to have more native tree species than any other region and any rainforest in the Hawaiian islands (Rock, 1913).

For decades, biologists have cited that over 90% of native Hawaiian dry forests have been destroyed (Bruegmann, 1996; Cordell et al., 2008); however, the actual current extent of native dry forest cover may be as low as 1% of the original (Pau, 2018). Thus, reducing the resiliency and redundancy of dry forests. Forty-five percent of the dry forest plant species in Hawai'i are at risk of

Fig. 3 Map of historical and current extent of dry forest in Islands of Moloka'i, Lāna'i, Maui and Kaho'olawe. Word from Reeves, M. K., and Amidon, F. (2018). Habitat status assessment methods—Hawai'i, current condition summaries. Technical report from United States Fish and Wildlife Service, Pacific Islands Fish and Wildlife Office, Honolulu, HI, pp. 439.

endangerment (Pau et al., 2009). Twenty-five percent of the endangered plant taxa in the Hawaiian islands are from the dry forests, and approximately 20% of dry land plant taxa in the Hawaiian Islands are known to be extinct (Cabin et al., 2000; Sakai et al., 2002), which has reduced the representation of this forest.

Most of the remaining and relatively intact native dry forests are currently found in areas that contained rough lava substrates that were unsuitable for ungulates (one of the stressors on dry forests, see below) to walk on thereby reducing the levels of browsing (Medeiros et al., 1993). Additionally, these areas were able to withstand fires because the young undeveloped substrates contained fewer invasive species, more particularly invasive grasses that serve as high fuel loads which are able to carry fires further into the forest (Medeiros et al., 1993).

The current extent of dry forests occurs on all of the main Hawaiian islands, but these forests are largely composed of a mixture of native /nonnative vegetation (Figs. 5 and 6). The island of Hawai'i contains the largest amount of dry forest in the main Hawaiian islands with >37,231 ha (92,000 ac), roughly 4% of the island and 2% of the area of all the main Hawaiian islands. Following the island of Hawai'i, Maui contains approximately 14,199 ha (35,087 ac) of dry forest. Ni'ihau contains the highest percent of dry forest related to island size at 71%, while Kaua'i has the least amount of dry forest at 3% compared to island size (Fig. 5, Table 2).

Roughly 29,127 ha (71,974 ac) of dry forests in Hawai'i are native species dominated (containing >50% native vegetation), with the majority (28,742 ha (71,023 ac)) located on the island of Hawai'i (Fig. 6). In comparison, approximately 68,188 ha (168,497 ac) of dry forests in Hawai'i are native/nonnative mixed and 6435 ha (15,902 ac) are classified as heavily disturbed (Fig. 6). Although, introduced dry forests are widespread, native dry forests are still found in both the lowland and montane-subalpine zones. Tree plantations are found on Kaua'i, O'ahu, Moloka'i, and the island of Hawai'i (Fig. 7).

Stressors

There are a number of stressors currently impacting dry forest. These stressors are listed here, and the most significant in this habitat are further explained in the below subsections:

- Invasive Ungulates
- Invasive Plants
- Plant Disease

Fig. 4 Map of historical and current extent of dry forest in the Island of O'ahu. Word from Reeves, M. K., and Amidon, F. (2018). Habitat status assessment methods—Hawai'i, current condition summaries. Technical report from United States Fish and Wildlife Service, Pacific Islands Fish and Wildlife Office, Honolulu, HI, pp. 439.

- Invasive Herbivores
- Fire
- Drought
- Natural Disasters
- Climate Change
- Agriculture and Urban Development

Invasive ungulates

Impacts to the native species and ecosystems of Hawai'i accelerated following first human contact with the arrival of Captain James Cook in 1778. The Cook expedition and subsequent explorers intentionally introduced a European race of pigs or boars and other livestock, such as goats, to serve as food sources for seagoing explorers (Tomich, 1986; Loope, 1998). The mild climate of the islands, combined with the lack of competitors or predators, led to the successful establishment of large populations of these invasive mammals, to the detriment of native Hawaiian species and ecosystems. The presence of these mammals is considered to be an extremely important cause in the decline of native plant communities and ecotypes in the Hawaiian islands (Cuddihy and Stone, 1990). Dry forests are currently threatened by the destruction or degradation due to invasive ungulates, including pigs, goats, axis deer, mouflon, and cattle.

The effects of ungulates include the destruction of vegetative cover; trampling of plants and seedlings; direct consumption of native vegetation; soil disturbance; dispersal of invasive plant seeds on hooves and coats, and through the spread of seeds in feces; and creation of open disturbed areas conducive to further invasion by invasive plant species. All of these impacts can lead to the subsequent conversion of a native plant community to one dominated by invasive species (Nogueira-Filho et al., 2009). Because ungulates inhabit terrain that is often steep and remote (Cuddihy and Stone, 1990), foraging and trampling contributes to severe erosion of watersheds and degradation of streams. As early as 1900, there was increasing concern expressed about the integrity of island watersheds due to effects of ungulates and other factors, leading to the establishment of a professional forestry program emphasizing soil and water conservation (Nelson, 1989).

Fig. 5 Distribution of dry forests in the main Hawaiian islands. Word from Reeves, M. K., and Amidon, F. (2018). Habitat status assessment methods—Hawai'i, current condition summaries. Technical report from United States Fish and Wildlife Service, Pacific Islands Fish and Wildlife Office, Honolulu, HI, pp. 439.

Invasive plants

Native vegetation on all of the main Hawaiian islands has undergone extreme alteration because of past and present land management practices, including ranching, the deliberate introduction of nonnative plants and animals, and agricultural development (Cuddihy and Stone, 1990). Over 800 plant taxa have been introduced from elsewhere, and nearly 100 of these have become pests (e.g., injurious plants) in Hawai'i (Smith, 1985; Cuddihy and Stone, 1990). Some of the nonnative plants were brought to Hawai'i by various groups of people, including the Polynesians, for food or cultural reasons. Plantation owners (and the territorial government of Hawai'i), alarmed at the reduction of water resources for their crops caused by the destruction of native forest cover by grazing feral and domestic animals, introduced nonnative trees for reforestation. Ranchers intentionally introduced pasture grasses and other nonnative plants for agriculture, and sometimes inadvertently introduced weeds as well. Other plants were brought to Hawai'i for their potential horticultural value (Scott et al., 1986; Cuddihy and Stone, 1990).

Invasive plants adversely affect microhabitat in the dry forest by modifying availability of light and nutrient cycling processes, and by altering soil-water regimes (Smith, 1985). Some invasive plants may release chemicals that inhibit growth of other plants. They also alter fire regimes leading to incursions of fire-tolerant, nonnative plant species in native ecotypes (Cuddihy and Stone, 1990; Smith, 1985). These competitive advantages allow invasive plants to convert native-dominated plant communities to nonnative plant communities (Cuddihy and Stone, 1990; Vitousek, 1992).

Plant disease

The primary plant disease that impacts dry forests are two species of the fungal genus *Ceratocystis* that cause mortality in 'ōhi'a, which is commonly referred to as rapid 'ōhi'a death (ROD). 'Ōhi'a is Hawai'i's most common and widespread native tree, occurring from sea level to 2500 m (8200 ft) elevation (Keith et al., 2015) and is often a dominant species in lowland and montane-subalpine dry

Fig. 6 Quality of dry forests in the main Hawaiian islands. Word from Reeves, M. K., and Amidon, F. (2018). Habitat status assessment methods—Hawai‘i, current condition summaries. Technical report from United States Fish and Wildlife Service, Pacific Islands Fish and Wildlife Office, Honolulu, HI, pp. 439.

Table 2 Current distribution of dry forests in the main Hawaiian islands

Island	Area (acres)	Percent of island	Percent of main Hawaiian islands
Kaho’olawe	13,657	48	< 1
Ni’ihau	32,624	71	1
Lāna’i	31,610	35	1
Moloka’i	21,281	13	1
Kaua’i	11,734	3	< 1
O’ahu	25,161	7	1
Maui	35,087	8	1
Hawai’i	92,516	4	2

Word from Reeves, M.K., and Amidon, F. (2018). Habitat status assessment methods—Hawai‘i, current condition summaries. Technical report from United States Fish and Wildlife Service, Pacific Islands Fish and Wildlife Office, Honolulu, HI, pp. 439.

forest. It is an ecologically important species that defines native forest succession and ecosystem function, provides habitat to many native species, and is culturally significant (Keith et al., 2015).

Rapid ‘ōhi’a death is a significant and poorly understood disease that was identified in 2012, and is only known to occur on the island of Hawai‘i. The disease causes browning in the crowns of ‘ōhi’a trees and ultimately leads to mortality. By the end of 2014, it was reported that approximately 2428 ha (6000 ac) of forest stands from Kalapana to Hilo showed > 50% mortality (Friday et al., 2015). And by 2017 approximately 30,351 ha (75,000 ac) showed symptoms of Rapid ‘ōhi’a death, including areas in Kona where dry forest occurs (CTAHR, 2018). Once a stand is infected, nearly 100% of the trees can succumb to the disease within 2–3 years

Fig. 7 Vegetation summary of dry forests in the main Hawaiian islands. Word from Reeves, M. K., and Amidon, F. (2018). Habitat status assessment methods—Hawai'i, current condition summaries. Technical report from United States Fish and Wildlife Service, Pacific Islands Fish and Wildlife Office, Honolulu, HI, pp. 439.

(CTAHR, 2018; Friday et al., 2015). Humans are thought to be a primary vector of transmission by moving infected wood, or contaminated tools, gear, and vehicles from one location to another (CTAHR, 2018). In addition, research has identified a nonnative ambrosia beetle as another likely vector. The beetles bore into trees and create a fine dust, referred to as frass, that can be carried by the wind and enter 'ōhi'a through wounds (CTAHR, 2018).

Invasive herbivores

One of the primary invasive herbivores that impact the dry forests are rats. There are three species of rats, all of which are introduced, in the Hawaiian islands: Polynesian rat (*Rattus exulans*), black rat (*Rattus rattus*), and Norway rat (*Rattus norvegicus*). The Polynesian and black rat are the most abundant rat species found in the wild, in dry to wet forests (Lindsey et al., 1999; Cole et al., 2000) and are the rodent species that have the most prominent impact in the dry forest. Rats are omnivorous and eat almost any type of food (Nelson, 2012). They impact native plants by eating fleshy fruits, seeds, flowers, stems, leaves, roots, and other plant parts (Atkinson and Atkinson, 2000), and by stripping bark and cutting small branches (twig cutting) in search of moisture and nutrients, seriously affecting vigor and regeneration (Abe and Umeno, 2011; Nelson, 2012). In the Hawaiian islands, rats may consume as much as 90% of the seeds produced by some native plants, and in some cases prevent regeneration of forest species completely (Cuddihy and Stone, 1990). Hawaiian plants as well as other plants from island ecosystems, are particularly susceptible to rat predation because they lacked native rodents, which can prevent successful reproduction (Cuddihy and Stone, 1990; Chimera and Drake, 2011). For the most part, rodents tend to target large seeds and since numerous dry forest plants contain fruits with one to few large seeds, rodents could be limiting seedling germination by the direct effect of seed mortality (Chimera and Drake, 2011). Given their impacts on native vegetation, rats have the potential to significantly alter dry forests and evidence of this is common in the dry forests of Hawai'i (Chimera and Drake, 2011).

The erythrina gall wasp (*Quadrastichus erythrinae*) is an invasive invertebrate that impacts dry forests, particularly the tree species *Erythrina variegata* (tall erythrina), *E. crista-galli*, and perhaps most importantly the native wiliwili. The erythrina gall wasp was first discovered on O'ahu in 2005 and subsequently spread to the other main Hawaiian islands (Heu et al., 2008). Like other gall-forming wasps, they insert their eggs into young leaf and stem tissue. The larvae develop and eventually cut exit holes to emerge as adults. Heavily galled plants result in a loss of growth and vigor, while severe infestations lead to defoliation and death (Heu et al., 2008; Yang et al., 2004). This species has been described as a destructive pest on native wiliwili trees, thus impacting dry forests.

The black twig borer (*Xylosandrus compactus*) also impact dry forests. This invasive pest was first discovered on O'ahu in 1961 and has become widespread throughout the main Hawaiian islands (Nelson and Davis, 1972). Black twig borers tunnel into woody twigs or branches to lay their eggs. This excavation and the introduction of pathogens damages the host, leading to die-back. Severe infestation can kill the host plants, including large trees (Tenbrink and Hara, 2007; Nelson and Davis, 1972). The black twig borer has been identified as a major threat to the native species *Mezoseuron kawaiense* (uhiuhi), *Alectryon macrococcus* (māhoe), *Nothocestrum latifolium* ('aiea), and *Flueggea neowawraea* (mēhamehame) (USFWS, 2013a,b, 2015, 2016a). Black twig borers have also infested invasive understory shrub species like koa haole, *Psidium guajava* (guava), and Christmas berry; as well as stands of nonnative tree species like *Lophostemon confertus* (brushbox), *Syncarpia glomulifera* (turpentine tree), *Melaleuca quinquenervia* (paperbark), *Eucalyptus sideroxylon* (red-ironbark eucalyptus), and *E. pilularis* (blackbutt eucalyptus) (Nelson and Davis, 1972).

Myoporum thrips or naio thrips (*Klambothrips myopori*) are a more recent invasive invertebrate to Hawai'i. It was first detected on the island of Hawai'i in 2008 attacking the native naio (HDLNR et al., 2013). The naio thrips feed on the host plant's foliage, resulting in leaf distortion and galls. Heavy infestations lead to leaf curling, dieback, defoliation, and mortality (HDLNR et al., 2013). Naio is a dominant species found in dry forests, and naio thrips have caused high levels of infestation and mortality on the species. In addition, naio mortality also impacts native fauna that rely on naio for food and/or habitat, such as insect herbivores and pollinators (HDLNR et al., 2013). Unfortunately in November 2018, naio thrips were detected on O'ahu by the Hawaii Department of Agriculture (HDLNR, 2019). A response team was implemented and infected trees were cut down, sprayed with insect killing soap, and then disposed of from the property. Efforts are underway to prevent naio thrips from further spreading across O'ahu and onto other islands.

Fire and drought

Fire is an increasing, human exacerbated threat to native species and ecosystems in Hawai'i. Fires inadvertently or intentionally set by the Polynesian settlers probably contributed to the initial decline of native vegetation in drier areas. These early settlers practiced slash-and-burn agriculture that created open lowland areas suitable for the opportunistic invasion and colonization of nonnative, fire-adapted grasses throughout the archipelago (Kirch, 1982; Cuddihy and Stone, 1990). Beginning in the late 18th century, Europeans and Americans introduced plants and animals that further degraded native Hawaiian ecosystems. Ranching and the creation of ranch lands in particular created highly fire-prone areas of nonnative grasses and shrubs (D'Antonio and Vitousek, 1992). Although fires were infrequent in mountainous regions, extensive fires occurred in lowland dry areas, leading to grass-fire cycles that converted native dry forest to nonnative grassland (D'Antonio and Vitousek, 1992).

Because of the greater frequency, intensity, and duration of fires that have resulted from the human alteration of landscapes and the introduction of nonnative plants, especially grasses, fires are now more destructive to native Hawaiian ecosystems (Brown and Smith, 2000), and a single grass-fueled fire often kills most native trees and shrubs in the area (D'Antonio and Vitousek, 1992). Fire destroys dormant seeds of these native species, as well as the individual plants themselves, even in steep, inaccessible areas or near streams and ponds. Successive fires remove habitat for native species by altering microclimate conditions, creating conditions more favorable to nonnative plants. Nonnative grasses (e.g., fountain grass), many of which may be fire-adapted, produce a high fuel load that allows fire to burn areas that would not otherwise burn easily, regenerate quickly after fire, and establish rapidly in burned areas (D'Antonio and Vitousek, 1992; Tunison et al., 2002). Native woody plants may recover to some degree, but fire tips the competitive balance toward nonnative species (National Park Service 1989 in Cuddihy and Stone, 1990; Takeuchi, 1991). Due to the seasonal drought conditions in the dry forest, the risk of fire and its associated impact is exacerbated and considered a significant stressor usually resulting in loss of forest land in favor of grassland.

Drought is also a stressor to the dry forests and is not uncommon in the Hawaiian islands. Drought is a cyclical weather phenomenon that is beyond human control. Between 1860 and 2016, there have been 38 periods of Statewide drought (Giambelluca et al., 1991; One World One Water, LLC, 2017). The most severe drought events over the past 15 years were associated with the El Niño phenomenon (Hawai'i State Civil Defense, 2011). Drought also leads to an increase in the number of forest and brush fires (Giambelluca et al., 1991), causing a reduction of native plant cover (D'Antonio and Vitousek, 1992) and a reduction in availability of host plants for invertebrates and other fauna. In addition, the increased risk for wildfires associated with drought brings the increased potential for all of its aforementioned impacts.

Natural disasters

In addition to their direct effects on plants, hurricanes exacerbate the impacts from other threats such as habitat modification and destruction by ungulates and competition with nonnative plants. By destroying vegetation, hurricanes open the forest canopy, thus modifying the availability of light, and create disturbed areas conducive to invasion by nonnative pest species (Asner and Goldstein, 1997; Harrington et al., 1997).

Climate change

Changes in environmental conditions that may result from global climate change include increasing temperatures, changing precipitation, and increasing storm intensities and frequencies. These changes may lead to the loss of native species due to direct physiological stress, the loss or alteration of habitat, or changes in disturbance regimes (e.g., droughts, fire, storms, and hurricanes). In a recent assessment of vulnerability to climate change, native Hawaiian plant species found primarily in dry forests were found to have higher vulnerability scores than species from any other habitat type (Fortini et al., 2013).

Agriculture and urban development

The consequences of past land use practices such as agricultural or urban development have resulted in little or no native vegetation below 600 m (2,000 ft) throughout the Hawaiian islands (TNCH, 2007), largely impacting the coastal and lowland dry ecosystems, including lowland dry forests. Although agriculture has been declining in importance, large tracts of former agricultural lands are being converted into residential areas or left fallow (TNCH, 2007). In addition, the population in Hawai'i has increased almost 10% in the past 10 years, further increasing demands on limited land and water resources on the islands (HDBEDT, 2013).

Conservation Efforts

Impacts from stressors are addressed through various management approaches such as active (on-the-ground) management (i.e., predator and invasive species control, fencing, reintroduction, etc.), land protections, laws and regulations, and education and outreach. These approaches are implemented by numerous government agencies (federal and state), private organizations, and nongovernmental organizations (NGOs). Given that land ownership of dry forest is spread among these parties (Fig. 8),

Fig. 8 Land ownership of dry forests in the main Hawaiian islands. Word from Reeves, M. K., and Amidon, F. (2018). Habitat status assessment methods—Hawai'i, current condition summaries. Technical report from United States Fish and Wildlife Service, Pacific Islands Fish and Wildlife Office, Honolulu, HI, pp. 439.

partnerships are also formed to manage the forest collectively. The following subsections detail many of the conservation efforts related to dry forests, however they do not encompass all that exist.

Federal

Endangered Species Act

The Endangered Species Act of 1973 (ESA) aims to provide a framework to conserve and protect endangered and threatened species and their habitats. As habitat loss is the primary threat to most imperiled species, the ESA allowed the US Fish and Wildlife Service (USFWS) and National Marine Fisheries Service (NMFS) to designate specific areas as critical habitat zones. In 1978, Congress amended the law to make critical habitat designation a mandatory requirement for all threatened and endangered species.

Approximately 13,098 ha (32,365 ac) of dry forests have been designated as federal critical habitat for 237 threatened and endangered species in the main Hawaiian islands (Fig. 9; Table 3). The majority of designated critical habitat that is also classified as dry forest is located on the island of Hawai'i at 8378 ha (20,702 ac) (Fig. 9). Species listed under the ESA are automatically added to the State of Hawai'i list of endangered species, and are thus also protected by State regulations.

Approximately 3821 ha (9442 ac) or 38% of dry forests are protected in reserve areas across the main Hawaiian islands (Fig. 10). Reserve areas are defined as those designated as parks and reserves. These may include areas designated as a national park, national wildlife refuge, NAR, or Nature Conservancy preserve (Reeves and Amidon, 2018). The amount of dry forest protected in reserve areas varies by island, with 2967 ha (7366 ac) or <5% on the island of Hawai'i to 31 ha (76 ac) or <5% on Kaua'i (Fig. 10). Of those 2967 ha (7366 ac) protected in reserves areas on the island of Hawai'i roughly 2716 ha (6711 ac) or <1% are classified as native dominated ecotype (Fig. 10). Ni'ihau and Kaho'olawe contain the least amount of dry forest protected in reserve areas in the State with <2 ha (4 ac) each or <4% (Fig. 10). Knowing that <3821 ha (9442 ac) of dry forests are protected in reserve areas in

**Fig. 10** Quality of dry forests designated as reserve areas in the main Hawaiian islands. Word from Reeves, M. K., and Amidon, F. (2018). Habitat status assessment methods—Hawai'i, current condition summaries. Technical report from United States Fish and Wildlife Service, Pacific Islands Fish and Wildlife Office, Honolulu, HI, pp. 439.

the State, and 106,703 ha (263,670 ac) are actually classified as dry forests in the State, indicates a need to implement additional measures to increase the public's awareness of the remaining gap between unprotected versus protected dry forests.

National parks

Lands managed by the National Park Service (NPS) (land ownership is summarized in [Fig. 8](#)) have benefited from ongoing management programs, which include invasive species control, research, and species-specific management. See [Table 4](#) for a list of protected dry forests in the NPSs and see [Table 5](#) for examples of conservation efforts being applied at each NPS. Protected parks include Haleakalā National Park on east Maui, which was established by Congress in 1916. The Park now protects > 33,000 ac of land on the island of Maui ([Haleakalā National Park, 2016](#)). Kalaupapa National Historical Park on Moloka'i is home to Kauhakō Crater, which contains the only known low elevation native/pristine dryland forest in the state ([HDLNR, 2015](#)). Hawai'i Volcanoes National Park (HVNP) was established by Congress in 1916. Hawai'i Volcanoes National Park encompasses diverse environments that range from sea level to the summit of Mauna Loa at 13,677 ft. and includes the active Kīlauea volcano ([National Park Service, 2015](#)). Some of the lowlands at HVNP contain small scattered stands of dry forest species on cliff faces, which are described in the dry cliff subtype of the Hawai'i's Dry Shrublands and Grasslands chapter.

National wildlife refuges

National Wildlife Refuges (NWR) are a national network of lands and waters managed by the USFWS for the conservation of fish, wildlife, and plant resources and their habitat. See [Table 4](#) for a list of protected dry forests in the NWRs in Hawai'i and [Table 5](#) for examples of conservation efforts being applied at NWRs.

State

Natural area reserves system

The Natural Area Reserves System (NARS) was established in 1970 with the intent to preserve in perpetuity specific land and water areas which support communities, as relatively unmodified as possible, of the natural flora and fauna, as well as geological sites, of Hawai'i. Natural Area Reserves (NAR) are State lands that are administered by the Division of Forestry and Wildlife (DOFAW) within the Department of Land and Natural Resources (DLNR). The State conducts some conservation management actions on these lands and provides access to others who are conducting such activities. See [Table 4](#) for a list of protected dry forests in the NARS of Hawai'i and [Table 5](#) for examples of conservation efforts being applied within each NAR.

Forest reserve system

The Forest Reserve System (FRS) was created by the Territorial Government of Hawai'i in 1903 as early foresters recognized the need to protect forests to provide water for agriculture and surrounding communities. This represented a public-private partnership to protect and enhance forested lands that is carried on today through the management of DOFAW as they focus their resources to protect, manage, restore, and monitor the natural resources of the FRS ([DOFAW, 2018a](#)). The FRS and Wildlife Sanctuaries contains over 274,624 ha (678,612 ac) of land of which approximately 11,201 ha (27,680 ac) or 4% are classified as dry forest. See [Table 4](#) for a list of protected dry forests in the FRS and Wildlife Sanctuaries, and [Table 5](#) for examples of conservation efforts being applied within each of these protected areas.

Landowner assistance programs

DOFAW implements a variety of landowner assistance programs for landowners willing to protect forest, wildlife, and watershed resources ([DOFAW, 2018b](#)). The Forest Stewardship Program (FSP) provides technical and financial assistance to private landowners to protect, manage, and restore important forest resources on their properties. The Conservation Reserve Enhancement Program (CREP) was created as an initiative under FSP to expand financial assistance to landowners and focuses on the restoration of agricultural lands and protection of sensitive habitats. Projects under these programs that include dry forest include the Waikoloa Dry Forest Initiative on the island of Hawai'i and a developing project in Palehua on O'ahu ([Waikoloa Dry Forest Initiative, 2015](#)). See [Table 5](#) for examples of conservation efforts being applied at Waikoloa Dry Forest.

Department of Hawaiian Home Lands

The Department of Hawaiian Home Lands (DHHL) was created by the Hawai'i State Legislature in 1960 and is governed by the Hawaiian Homes Commission Act of 1920. DHHL views its responsibility as a landowner to manage and protect native lands "to support both cultural and resource management activities and create homesteading opportunities for the future" ([DHHL, 2009](#)). Thus, the 'Āina Mauna Legacy Program was created to protect native forest on the slopes of Mauna Kea on the island of Hawai'i. The program specifically includes the lands of Humu'ula and Pi'ihonua, which contain tracts of dry forest. See [Table 5](#) for examples of conservation efforts being applied by the 'Āina Mauna Legacy Program.

Office of Hawaiian Affairs

The Office of Hawaiian Affairs (OHA) is a public agency responsible for improving the well-being of Native Hawaiians. OHA accomplishes this by collaborating with various organizations to strengthen community resources, including natural and cultural resources. One example is OHA's role as a funder for a dryland forest restoration project in Ka'ūpūlehu on the island of Hawai'i.

Table 4 Protected dry forest in the main Hawaiian Islands.

<i>Island</i>	<i>Ownership</i>	<i>Location</i>	<i>Protected dry forest acreage (ha(ac))^{a,b}</i>	<i>Dry forest conservation importance^{a,b,c,d}</i>
Moloka'i	National Park Service	Kalaupapa National Historical Park	159 ha (~392 ac)	Kauhakō Crater; 1 ha (3 ac) of closed 'ōhi'a dry forest, 84 ha (206 ac) of kiawe dry forest; 1 ha (3 ac) of mixed native and nonnative dry forest; 73 ha (180 ac) of nonnative dry forest
Hawai'i	National Park Service	Hawai'i Volcanoes National Park	2083 ha (5147 ac)	1 ha (2 ac) kiawe dry forest; 1267 ha (3132 ac) mixed māmane-naio and other native trees; 4 ha (10 ac) nonnative dry forest; 119 ha (293 ac) open koa-māmane dry forest; 692 ha (1710 ac) of open 'ōhi'a dry forest
Hawai'i	National Park Service	Kaloko-Honokōhau National Historical Park	35 ha (87 ac)	35 ha (87 ac) of kiawe dry forest
Hawai'i	National Park Service	Pu'u'honua o Hōnaunau National Historical Park	8 ha (19 ac)	4 ha (10 ac) of closed 'ōhi'a dry forest; 4 ha (9 ac) of kiawe dry forest
Kaua'i	Fish and Wildlife Services	Kilauea Point National Wildlife Refuge	5 ha (13 ac)	5 ha (13 ac) of kiawe dry forest
Kaua'i	Fish and Wildlife Services	Hanalei National Wildlife Refuge	2 ha (6 ac)	2 ha (6 ac) of kiawe dry forest
O'ahu	Fish and Wildlife Services	James Campbell National Wildlife Refuge	61 ha (149 ac)	13 ha (31 ac) of kiawe dry forest; 48 ha (118 ac) of nonnative dry forest
O'ahu	Fish and Wildlife Services	Pearl Harbor National Wildlife Refuge Kalaeloa Unit	8 ha (20 ac)	6 ha (16 ac) of kiawe dry forest; 2 ha (4 ac) of nonnative dry forest
Moloka'i	Fish and Wildlife Services	Kakahai'a National Wildlife Refuge	4 ha (11 ac)	4 ha (11 ac) of kiawe dry forest
Maui	Fish and Wildlife Services	Kealia Pond National Wildlife Refuge	4 ha (10 ac)	4 ha (10 ac) of kiawe dry forest
Hawai'i	Fish and Wildlife Services	Hakalau Forest National Wildlife Refuge and South Kona Section	51 ha (124 ac)	11 ha (26 ac) of mixed māmane-naio and other native trees; 40 ha (98 ac) of open koa-māmane dry forest
Kaua'i	State Department of Land and Natural Resources	Nāpali Coast State Wilderness Park	22 ha (54 ac)	4 ha (9 ac) of kiawe dry forest; 18 ha (45 ac) of nonnative dry forest
O'ahu	State Department of Land and Natural Resources	Ka'ena Point Natural Area Reserve	2 ha (5 ac)	2 ha (5 ac) of kiawe dry forest
O'ahu	State Department of Land and Natural Resources	Hāmākua Marsh Wildlife Sanctuary	2 ha (4 ac)	2 ha (4 ac) of nonnative dry forest
O'ahu	State Department of Land and Natural Resources	Pouhala Marsh Wildlife Sanctuary	1 ha (3 ac)	1 ha (3 ac) of nonnative dry forest
Moloka'i	State Department of Land and Natural Resources	Oloku'i Natural Area Reserve	17 ha (41 ac)	17 ha (41 ac) of kiawe dry forest
Maui	State Department of Land and Natural Resources	Kanaio Natural Area Reserve	10 ha (~25 ac)	In a 1993 survey, contained lama dry forest and wiliwili dry forest. 10 ha (25 ac) of kiawe dry forest
Maui	State Department of Land and Natural Resources	West Maui Natural Area Reserve	8 ha (20 ac)	8 ha (20 ac) of nonnative dry forest
Maui	State Department of Land and Natural Resources	'Āhihi-Kīna'u Natural Area Reserve	34 ha (84 ac)	30 ha (75 ac) of kiawe dry forest; 4 ha (9 ac) of nonnative dry forest
Hawai'i	State Department of Land and Natural Resources	Kīpāhoehoe Natural Area Reserve	48 ha (119 ac)	11 ha (28 ac) of mixed māmane-naio and other native trees dry woodland; 26 ha (63 ac) of open koa-māmane dry forest; 11 ha (28 ac) of open 'ōhi'a dry forest
Hawai'i	State Department of Land and Natural Resources	Mauna Kea Ice Age Natural Area Reserve	1 ha (~2 ac)	1 ha (2 ac) of mixed māmane-naio and other native trees
Hawai'i	State Department of Land and Natural Resources	Kīpuka 'Āinahou Nēnē Sanctuary	42 ha (105 ac)	41 ha (102 ac) of mixed māmane-naio and other native trees; 1 ha (3 ac) of open koa-māmane dry forest
Hawai'i	State Department of Land and Natural Resources	Manukā Natural Area Reserve	580 ha (1433 ac)	187 ha (462 ac) of closed 'ōhi'a dry forest; 56 ha (139 ac) of kiawe dry forest; 70 ha (173 ac) of mixed māmane-naio and other native trees; 4 ha (10 ac) of nonnative dry forest; 13 ha (32 ac) of open koa-māmane dry forest; 250 ha (617 ac) of open 'ōhi'a dry forest

Table 4 Protected dry forest in the main Hawaiian Islands.—cont'd

<i>Island</i>	<i>Ownership</i>	<i>Location</i>	<i>Protected dry forest acreage (ha(ac))^{a,b}</i>	<i>Dry forest conservation importance^{a,b,c,d}</i>
Hawai'i	State Department of Land and Natural Resources	Pu'u Wa'awa'a Wildlife Sanctuary	6 ha (> 14 ac)	6 ha (14 ac) of mixed māmane-naio and other native trees. Tracts of montane dry and lowland dry forest
Hawai'i	State Department of Land and Natural Resources	Pu'u Maka'ala Natural Area Reserve	67 ha (166 ac)	66 ha (164 ac) of mixed māmane-naio and other native dry forest trees; 1 ha (2 ac) of open koa-māmane dry forest
Moloka'i	The Nature Conservancy	Kamakou Preserve	3 ha (7 ac)	3 ha (7 ac) of kiawe dry forest
Moloka'i	The Nature Conservancy	Pelekunu Preserve	18 ha (44 ac)	18 ha (44 ac) of kiawe dry forest
Moloka'i	The Nature Conservancy	Mo'omomi Preserve	211 ha (521 ac)	211 ha (521 ac) of kiawe dry forest
Lāna'i	The Nature Conservancy	Kānepu'u Preserve	29 ha (72 ac)	5 ha (13 ac) of kiawe dry forest; 23 ha (57 ac) of nonnative dry forest; 1 ha (2 ac) of open 'ōhi'a dry forest
Maui	The Nature Conservancy	Waikamoi Preserve	1 ha (3 ac)	1 ha (3 ac) of kiawe dry forest
Hawai'i	The Nature Conservancy	Kīholo Preserve	1 ha (3 ac)	1 ha (3 ac) of kiawe dry forest
Hawai'i	The Nature Conservancy	Kamehame Preserve	2 ha (6 ac)	2 ha (6 ac) of kiawe dry forest
Hawai'i	The Nature Conservancy	Kona Hema Preserve	26 ha (63 ac)	11 ha (26 ac) of mixed māmane-naio and other native dry forest; 15 ha (37 ac) of open koa-māmane dry forest
Hawai'i	The Nature Conservancy	Kīpuka a 'Umi Preserve	2 ha (4 ac)	2 ha (4 ac) of mixed māmane-naio and other native dry forest
Maui	National Park Service	Haleakalā National Park	6614 ha (~16,343 ac)	810 ha (2000 ac) of lowland dry forest; 5649 ha (13,960 ac) of montane-subalpine dry forest; 137 ha (339 ac) of kiawe (<i>Prosopis pallida</i>) dry forest; 18 ha (44 ac) of nonnative dry forest

OHA awarded \$172,262 to the Hawai'i Forest Institute to support the restoration of native dryland lama forest in Ka'ūpūlehu. The project aims to foster relationships between community and 'āina (land) through utilizing educational stewardship, traditional knowledge, and scientific methods ([Hawai'i Forest Institute, 2017](#)).

Private

The Nature Conservancy

The mission of The Nature Conservancy (TNC) is to protect the lands and water on which all life depends. The Nature Conservancy of Hawai'i (TNCH) has 11 preserves in the State of Hawai'i encompassing > 16,187 ha (40,000 ac) ([TNCH, 2015](#)). See [Table 4](#) for a list of protected dry forests found within TNCs Preserves and [Table 5](#) for examples of conservation efforts being applied within each of the Preserves.

Kamehameha Schools

Kamehameha Schools (KS) is the largest private landowner in the State of Hawai'i with landholdings of over 147,710 ha (365,000 ac). Approximately 99% of this land is designated for agricultural (71,585 ha (176,890 ac)) or conservation (73,521 ha (181,675 ac)) purposes ([Kamehameha Schools, 2014](#)). In addition, roughly 19,425 ha (48,000 ac) or 13% is classified as dry forest with the majority located on the Kona side of the island of Hawai'i. Kamehameha Schools partners with many other conservation organizations to enhance stewardship of their resources. For example, KS has collaborated with the Three Mountain Alliance and the Hawaiian Silversword Foundation to protect montane-subalpine dry forest in Lupea (Kona side) on the island of Hawai'i ([Kamehameha Schools, 2011](#)). Examples of conservation efforts being applied at Kamehameha Schools are found in [Table 5](#).

Table 5 Examples of conservation efforts in dry forests.

<i>Organization/agency name</i>	<i>Location, island</i>	<i>Organization type</i>	<i>Conservation efforts^a</i>	<i>Target stressor(s)</i>
National Park Service	Hawai'i Volcanoes National Park, Hawai'i	Federal	Fencing, ungulate control, restoration	Invasive species
National Park Service	Kalaupapa National Historical Park, Moloka'i	Federal	Fencing, invasive plant and ungulate control, restoration, outplanting	Invasive species
National Park Service	Haleakalā National Park, Maui	Federal	Fencing, ungulate removal, invasive predator and plant control, surveys for listed species	Invasive species
National Park Service	Kaloko-Honokōhau National Historical Park, Hawai'i	Federal	Habitat restoration, research, invasive plant control, monitoring	Invasive species
National Park Service	Pu'uhonua o Hōnaunau National Historical Park, Hawai'i	Federal	Habitat restoration, invasive plant control, monitoring	Invasive species
US Fish and Wildlife Service	Hanalei National Wildlife Refuge, Kaua'i	Federal	Invasive plant control, endangered species management, habitat enhancement, predator control, monitoring	Invasive species
US Fish and Wildlife Service	Kilauea Point National Wildlife Refuge, Kaua'i	Federal	Invasive plant control, endangered species management, habitat enhancement, predator control, monitoring, outreach and education, predator-proof fence	Invasive species
US Fish and Wildlife Service	James Campbell National Wildlife Refuge, O'ahu	Federal	Habitat restoration and endangered species protection, predator and invasive plant control, monitoring	Invasive species
US Fish and Wildlife Service	Pearl Harbor National Wildlife Refuge, Kalaeloa Unit, O'ahu	Federal	Habitat restoration and endangered species protection, predator and invasive plant control, monitoring	Invasive species
US Fish and Wildlife Service	Kakahai'a National Wildlife Refuge, Moloka'i	Federal	Education, habitat restoration, invasive species control	Invasive species
US Fish and Wildlife Service	Hakalau Forest National Wildlife Refuge and South Kona Section, Hawai'i	Federal	Habitat restoration, fencing, ungulate and invasive plant control, propagation and outplanting, vegetation monitoring	Invasive species

Auwahi Forest Restoration Project

The Auwahi Forest Restoration Project began in 1997, as a collaboration between ʻUlupalakua Ranch, US Fish and Wildlife Service (USFWS), US Department of Agriculture (USDA), regional scientists, and volunteers to develop technologies for restoration of nonnative pastoral lands back to native dry forest. Examples of conservation efforts being applied at Auwahi Forest are found in **Table 5**.

Hawaiian Islands Land Trust

The Hawaiian Islands Land Trust (HILT) is a nonprofit 501(c)(3) land conservancy organization. It was formed in 2011 and helps to protect >7284 ha (18,000 ac) on Maui, Kaua'i, O'ahu, Moloka'i, and the island of Hawai'i. These conservation easements held in perpetuity by HILT help to conserve scenic views, agricultural resources, wildlife habitats, water resource areas, cultural and historical values, and outdoor recreation opportunities ([Hawaiian Islands Land Trust, 2018a](#)). On Maui, >32 ha (80 ac) of lowland dry forest and wetlands are protected at Nu'u refuge on east Maui through lands owned by the HILT ([Hawaiian Islands Land Trust, 2018b](#)). See **Table 5** for examples of conservation efforts being applied at Nu'u refuge.

Lānaʻi

The island of Lānaʻi is almost entirely under private ownership but does have conservation partnerships with the USFWS, the state of Hawaiʻi, and The Nature Conservancy. Currently the land manager, Pūlamā Lānaʻi, is implementing actions that benefit dry forests (USFWS, 2016b; Lānaʻi Resorts et al., 2015, in litt.). See [Table 5](#) for a list of these actions.

Multiple agency partnerships

Association of watershed partnerships

Watershed Partnerships are voluntary alliances of public and private landowners committed to protecting over 809,371 ha (2 million ac) of the most important watershed lands in Hawaiʻi of which approximately 52,487 ha (129,700 ac) is dry forest. Individual watershed partnerships have been established on five islands (island of Hawaiʻi, Maui, Molokaʻi, Oʻahu, and Kauaʻi) and jointly form the Hawaiʻi Association of Watershed Partnerships, to support statewide needs. A list of conservation actions happening through these partnerships are found in [Table 5](#).

Invasive species committees

Invasive species committees (ISCs) are voluntary partnerships of government, private and nonprofit organizations, and concerned individuals working to address invasive species issues in Hawaiʻi. These committees have been formed on individual islands (island of Hawaiʻi/Big Island [BIISC], Maui [MISC], Molokaʻi [MoMISC], Oʻahu [OISC], Kauaʻi [KISC]) and focus on the specific issues of their island. The overall goal of the ISCs is to “prevent, eradicate, or control priority incipient plant and animal species that threaten Hawaiʻi’s most intact federal, state, and private conservation lands” (HDLNR, 2015). For example, fountain grass has been identified as a target species for OISC and cooperative project species (work with others to control) for BISC (BISC, 2018; OISC, 2018). See [Table 5](#) for a list of conservation actions undertaken by ISCs.

Laws and regulations

Inadequate protection from introduction of nonnative species

Currently, four agencies are responsible for inspection of goods arriving in Hawaiʻi (CGAPS, 2009): Hawaiʻi Department of Agriculture (HDOA), US Department of Homeland Security-Customs and Border Protection (CBP), US Department of Agriculture-Animal and Plant Health Inspection Service-Plant Protection and Quarantine (USDA-APHIS-PPQ), and USFWS. A summary of each agencies responsibility can be found in [Table 6](#).

The State of Hawaiʻi’s unique biosecurity needs are not recognized by Federal import regulations. Under the USDA-APHIS-PPQ’s commodity risk assessments for plant pests, regulations are based on species considered threats to the mainland United States and do not address many species that could be pests in Hawaiʻi (Hawaiʻi Legislative Reference Bureau (HLRB, 2002; USDA-APHIS-PPQ, 2010; CGAPS, 2009). Interstate commerce provides the pathway for invasive species and commodities infested with nonfederal quarantine pests to enter Hawaiʻi. Pests of quarantine concern for Hawaiʻi may be intercepted at ports in Hawaiʻi by Federal agents but are not always acted on by them because these pests are not regulated under Federal mandates. Hence, Federal protection against pest species of concern to Hawaiʻi has historically been inadequate. It is possible for the USDA to grant Hawaiʻi protective exemptions under the “Special Local Needs Rule,” when clear and comprehensive arguments for both agricultural and conservation issues are provided; however, this exemption procedure operates on a case-by-case basis and is extremely time-consuming to satisfy. Therefore, that avenue may only provide minimal protection against the large diversity of foreign pests that threaten Hawaiʻi.

Adequate staffing, facilities, and equipment for Federal and State pest inspectors and identifiers in Hawaiʻi devoted to invasive species interdiction are critical biosecurity gaps (HLRB, 2002; USDA-APHIS-PPQ, 2010; CGAPS, 2009). State laws have recently been passed that allow the HDOA to collect fees for quarantine inspection of freight entering Hawaiʻi (e.g., Act 36 (2011) H.R.S. 150A-5.3). Legislation enacted in 2011 (H.B. 1568) requires commercial harbors and airports in Hawaiʻi to provide biosecurity and to facilitate cargo inspections.

Nonnative Vertebrate Species: The laws in the State of Hawaiʻi prohibit the importation of all animals unless they are specifically placed on a list of allowable species (HLRB, 2002; CGAPS, 2011). The importation and interstate transport of invasive vertebrates is federally regulated by the USFWS under the Lacey Act as “injurious wildlife” (Fowler et al., 2007); the current list of vertebrates considered as “injurious wildlife” is provided at 50 CFR 16. The existing vertebrate pest species previously mentioned are already well established and therefore not responsive to these biosecurity measures. However, the law in its current form has limited effectiveness in preventing new invasive vertebrate introductions into the State of Hawaiʻi.

Nonnative Invertebrate Species: The introduction of most invasive invertebrate pests to the State has been and continues to be accidental and incidental to other intentional and permitted activities. Although Hawaiʻi State government and Federal agencies have regulations and some controls in place (see above), the introduction and movement of invasive invertebrate pest species between islands and from one watershed to the next continues. For example, an average of 20 new nonnative invertebrate species were introduced to Hawaiʻi per year since 1970, an increase of 25% over the previous totals between 1930 and 1970 (TNCH, 1992). Existing regulatory mechanisms therefore appear inadequate to ameliorate the threat of introductions of nonnative invertebrates, and we have no evidence to suggest that any change to this situation is anticipated in the future. The introduction of nonnative invertebrates to the State of Hawaiʻi is a significant risk to dry forests.

Table 6 Examples of conservation efforts related to laws and regulations in dry forests.

<i>Conservation method</i>	<i>Target stressor</i>	<i>Summary of actions^a</i>
Hawai'i Department of Agriculture (HDOA)	Inadequate protection from introduction of nonnative species	Inspects domestic cargo and vessels and focuses on pests of concern to Hawai'i, especially insects or plant diseases not yet known to be present in the State
US Department of Homeland Security-Customs and Border Protection (CBP)	Inadequate protection from introduction of nonnative species	Inspecting commercial, private, and military vessels and aircraft and related cargo and passengers arriving from foreign locations. Quarantine issues involving nonpropagative plant materials (processed and unprocessed); wooden packing materials, timber, and products; internationally regulated commercial species under the Convention in International Trade in Endangered Species (CITES); federally listed noxious seeds and plants; soil; and pests of concern to the greater United States., such as pests of mainland United States. forests and agriculture
US Department of Agriculture-Animal and Plant Health Inspection Service-Plant Protection and Quarantine (USDA-APHIS-PPQ)	Inadequate protection from introduction of nonnative species	Inspects propagative plant material, provides identification services for arriving plants and pests, conducts pest risk assessments, trains CBP personnel, conducts permitting and preclearance inspections for products originating in foreign countries, and maintains a pest database that, again, has a focus on pests of wide concern across the United States
US Fish and Wildlife Service	Inadequate protection from introduction of nonnative species	Inspects arriving wildlife products, enforces the injurious wildlife provisions of the Lacey Act (18 U.S.C. 42; 16 U.S.C. 3371 et seq.), and prosecutes CITES violations

^aHawai'i Department of Agriculture (HDOA). (2009). Plant guidelines for importation to Hawai'i. Available at <http://hawaii.gov/hdoa/pi/pq/pq.plants>.

Word from Miller, S. E. (2018). Defining the foreseeable future for Pacific Islands habitat status assessments. June 2018 technical report. U.S. Fish and Wildlife Service, Pacific Islands Fish and Wildlife Office, Honolulu, HI, pp. 13.

Nonnative Plant Species: The State of Hawai'i allows the importation of most plant taxa, with limited exceptions, if shipped from domestic ports (HLRB, 2002; USDA-APHIS-PPQ, 2010; CGAPS, 2009). Hawai'i's plant import rules (H.A.R. 4–70) regulate the importation of 13 plant taxa of economic interest; regulated crops include pineapple, sugarcane, palms, and pines. Certain horticultural crops (e.g., orchids) may require import permits and have pre-entry requirements that include treatment or quarantine or both either prior to or following entry into the State. The State noxious weed list (H.A.R. 4–68) and USDA-APHIS-PPQ's Restricted Plants List restrict the import of a limited number of noxious weeds. If not specifically prohibited, current Federal regulations allow plants to be imported from international ports with some restrictions. The Federal Noxious Weed List (see 7 CFR 360.200) includes few of the many globally known invasive plants, and plants in general do not require a weed risk assessment prior to importation from international ports. The USDA-APHIS-PPQ is in the process of finalizing rules to include a weed risk assessment for newly imported plants. Although the State has general guidelines for the importation of plants, and regulations are in place regarding the plant crops mentioned above, the intentional or inadvertent introduction of invasive plants outside the regulatory process and movement of species between islands and from one watershed to the next continues. In addition, government funding is inadequate to provide for sufficient inspection services and monitoring. Therefore, the potential for invasive plants to adversely impact the dry forests due to a lax in State and Federal regulations will continue until the regulatory process is revised and additional funding is provided to support inspection services and monitoring at our ports.

General invasive species control actions

The Hawai'i Invasive Species Council (HISC), which was created by gubernatorial executive order in 2002, to coordinate local initiatives for the prevention and control of invasive species by providing policy level direction and planning for the State departments responsible for invasive species issues. In 2003, the Governor signed into law Act 85, which conveys statutory authority to the HISC to continue to coordinate approaches among the various State and Federal initiatives for the prevention and control of invasive species (HDLNR, 2003; HISC, 2009; H.R.S. 194–2(a)). Some of the recent priorities for the HISC include interagency efforts to control nonnative species such as naio thrips (HISC, 2009). In early 2009, HISC projected that, due to a tighter economy in Hawai'i and anticipated budget cuts in State funding support of up to 50%, there will be a serious setback in conservation achievements, and the loss of experienced, highly trained staff (HISC, 2009).

In 1995, the Coordinating Group on Alien Pest Species (CGAPS), a partnership comprised primarily of managers from every major Federal, State, County, and private agency and organization involved in invasive species work in Hawai'i, was formed in an effort to improve communication, increase collaboration, and promote public awareness (CGAPS, 2009).

Future Scenarios

The condition of dry forests in the foreseeable future is based on potential changes in three conservation management parameters (CMPs). These conservation parameters capture the social and legal mechanisms under which natural resource conservation is carried out. The CMPs are as follows:

1. *Conservation Values*: stakeholder involvement and public opinion determine the formulation, implementation and funding of natural resource conservation within laws and development plans.
2. *Laws and Biosecurity*: national, state, county, and city laws and regulations are the means by which natural resource conservation and biosecurity are supported and implemented (e.g., hunting regulations, Clean Water Act, Endangered Species Act, and local laws, etc.).
3. *Development or Conservation Planning*: national, state, county, city, and private development plans or conservation plans define specific actions that result in losses or gains in natural resource conservation and biosecurity (impacts are only realized at the time of implementation).

These conservation management parameters are critical factors that drive the direction and magnitude of natural resource conservation, and determine foreseeable future scenarios. The year 2035 is the extent of the “foreseeable future,” and is based on the projected divergence of IPCC Representative Concentration Pathway (RCP) climate change scenarios (van Vuren et al., 2011a,b; Miller, 2018).

The four foreseeable future scenarios considered in this assessment are:

Future Scenario One, Status Quo—the most likely foreseeable future; no change in natural resource conservation in the CMPs, so the current rate of change in land cover continues through the foreseeable future.

Future Scenario Two—a slight increase in natural resource conservation in the CMPs marginally improves conservation management.

Future Scenario Three—a slight to moderate decrease in conservation actions in the CMPs substantially decreases conservation management.

Future Scenario Four—a moderate to large increase in conservation actions in the CMPs substantially improves conservation management.

The future condition of Dry Forests in Scenario One, the status quo, was characterized from an assessment of change over time in Dry Forest land cover obtained from existing land cover maps (Amidon and Reeves, 2018). Based on these land cover maps, an annual rate of change for Dry Forest was estimated, and a projected change (in acres/ha) was calculated for the year 2035. The resulting information on changes in land cover by 2035, as derived from existing land cover change estimates, is the extent of the Dry Forest that is expected in the foreseeable future under Scenario One where conservation efforts remain unchanged and the current rate of change in land cover is also unchanged.

The future conditions of Dry Forest for Scenarios Two, Three, and Four cannot be quantitatively (acres/ha) estimated. However, the Scenario One estimate can provide a “baseline” for a qualitative characterization of changes in the future condition of Dry Forest under Scenarios Two, Three, and Four.

Changes in human population are captured only by the changes in the “developed” land cover footprint derived from land cover map analysis (Amidon and Reeves, 2018). Impacts from other sources of human activities or human-caused ecotype stressors (e.g., plant and animal diseases, wildfires, invasive species, etc.) are not well characterized in the land cover changes, but significantly contribute to increases in the land cover area dominated by nonnative vegetation.

Also, note that island-wide implementation of the CMPs is unlikely to have a significant effect on climate-related stressors (temperature, precipitation, and severe weather) resulting from global warming by 2035. This lack of CMP climate effects is due to the global lag in climate response to changes in greenhouse gas emissions which occurs on the order of centuries rather than years (Solomon et al., 2009; Gillett et al., 2011; Jevrejeva et al., 2012). Evidence of climate effects is also confounded by the large annual variation in the Pacific islands climate parameters, which is much greater than projected climate change by 2035. Although impacts from climate-related ecotype stressors do not change across the four scenarios, they were included in this analysis because of their overall magnitude of potential importance to future ecotype viability.

Future Scenario One—Status Quo.

Under Scenario One there is no change in the implementation of the three CMPs between 2018 and 2035. A continuing current rate of change in land cover through this foreseeable future results in a slow but continuous change in dry forest subcategories. See Table 7 for responses of Dry Forest stressors under Scenario One and Table 8 for a summary of change in quality and quantity of each dry forest subtype under Scenario One.

Redundancy is defined as the ability to withstand catastrophic events and is measured by the number and distribution of dry forests across representative areas. In this scenario, native dry forests would have a continued decline in size and distribution, and therefore a decrease in redundancy. Human-caused stressors will have a small increase overall and continue to reduce the

Table 7 Responses of dry forest stressors in foreseeable future scenarios

Conservation Management Parameters (CMPs)				
Conservation Values	Stakeholder involvement and public opinion influence the formulation, implementation, and funding of natural resource conservation and biosecurity (NRC/B) within laws and development or conservation plans.			
Laws and Biosecurity	National, state, county, and city laws and regulations are the means by which NRC/B are supported and implemented.			
Planning for Development or Conservation	National, state, county, city, and private development plans or conservation plans define actions that result in losses or gains in NRC/B (impacts realized at implementation).			
Foreseeable Future Scenarios and the resulting Dry Forest conditions				
Use Foreseeable Future	Scenario One:	Scenario Two:	Scenario Three:	Scenario Four:
Scenario One as a “baseline” to characterize changes in Conservation	CMPs: unchanged in support for NRC/B.	CMPs: small increase in support for NRC/B.	CMPs: small to moderate decrease in support for NRC/B.	CMPs: moderate to large increase in support for NRC/B.
Actions and Habitat Conditions in Future Scenarios Two, Three and Four.	Conservation Actions: no change; current rate of land cover change continues through the foreseeable future. Habitat Condition: habitat area, quality, and sustainability slowly decrease through the foreseeable future.	Conservation Actions: marginal increase. Habitat Condition: habitat area is unchanged through the foreseeable future; habitat quality and sustainability are slightly enhanced through the foreseeable future.	Conservation Actions: substantial decrease. Habitat Condition: urban and agricultural uses are prioritized over conservation; habitat area, quality, and sustainability substantially decrease through the foreseeable future.	Conservation Actions: substantial increase. Habitat Condition: robust, sustained effort to restore, manage, and expand conservation; habitat area, quality, and sustainability substantially increase through the foreseeable future.
Habitat stressors				
Development	small to moderate increase	no change (redevelop)	moderate to large increase	small to moderate decrease
Invasive Species	small increase	small increase	larger increase	small decrease
Plant Diseases	small increase	small increase	larger increase	no change to small decrease
Fire	small increase	small increase	larger increase	no change to small increase
Climate				
Temperature	small to moderate increase	small to moderate increase	small to moderate increase	small to moderate increase
Precipitation	small decrease	small decrease	small decrease	small decrease
Storms	small increase	small increase	small increase	small increase

Table 8 Summary of change in quality and quantity of dry forest subtypes in foreseeable future scenarios.

<i>Subtype</i>	<i>Scenario One: status quo</i>	<i>Scenario Two: slightly improved</i>	<i>Scenario Three: substantially decreased</i>	<i>Scenario Four: substantially improved</i>
Lowland native dry forests	Decrease	Slightly decrease	Severely decrease	Increase
Montane-subalpine native dry forests and woodlands	Decrease	Slightly decrease	Severely decrease	Increase
Introduced dry forests	Slightly increase	Slightly increase	Decrease	Decrease
Managed tree plantations	Slightly increase	Unchanged	Increase	Unchanged

size and quality of native dry forests. Ecological function is predicted to be reduced due to the ability of invasive plants and animals to outcompete native plants for water and space, subsequently resulting in a reduction in native biodiversity. Degradation of native dry forests will continue to increase as remaining areas become more fragmented, thus reducing their resiliency and representation.

Introduced dry forests are predicted to increase in size and distribution (redundancy) as a result of the overall small increase in human-caused ecotype stressors. Introduced dry forests are likely to expand as invasive species replace native-dominated communities, resulting in an increase in resiliency, redundancy, and representation.

The Tree plantations are predicted to slightly increase in size and distribution due to the assumed expansion of the human population and continued development pressure for forest products (lumber, fuel), horticulture, and agriculture (coffee, fruit, nut orchards resulting in a slight increase in resiliency, redundancy, and representation.

Future Scenario Two—there is a slight increase in the CMPs that marginally improves conservation management.

Under Scenario Two, conservation agencies and stakeholders work with increased but limited resources to slow or stop the degradation of landscape areas. Scenario Two is essentially ‘status quo’ with minor improvements in the three CMPs. This scenario is expected to have the second highest likelihood of occurring into the foreseeable future, being slightly less likely than Scenario

One. The anticipated changes, under Scenario Two, for each ecotype stressors important to Dry Forests are given in [Table 7](#). A summary of the change in quality and quantity of each dry forest subtype under Scenario One can be found in [Table 8](#).

Future Scenario Three—there is a small to moderate decrease in conservation actions in the CMPS that substantially decreases conservation management.

All natural resource management actions in the CMPs are set aside in deference to land use for economic development. With extensive localized management, some native species may persist in park-like settings or in areas where land development is not possible. This scenario has substantial declines in natural resource conservation within the three CMPs. An increasing human population is supported in its use of land for economic development over the conservation of native ecotypes. Areas that cannot support development become the only areas of free-living native species. The anticipated changes, under Scenario Three, for each ecotype stressors important to Dry Forests are given in [Table 7](#).

Overall, this scenario would severely degrade and fragment native dry forest and result in reduced resiliency, redundancy, and representation. However, this scenario, along with Scenario Four, has the lowest likelihood of occurring in the foreseeable future. See [Table 8](#) for a summary of change in quality and quantity of each dry forest subtype under Scenario Three.

Future Scenario Four—There is a moderate to large increase in conservation actions in the CMPS that substantially improves conservation management.

For this scenario, substantial improvements to the three CMPs and a general decrease in human-caused habitat stressors would increase the size and quality (resiliency) of lowland native dry forests and montane-subalpine native dry forests. Although this increase in native forest subtypes would be gradual at first it will become more noticeable by 2035 as the substantial improvements to the three CMPs will help keep these subtypes from declining (see [Table 8](#)).

Based on this analysis, the substantial improvements in restoration for native dry forest would result in increased resiliency, redundancy, and representation. However, as mentioned above, this scenario and Scenario Three have the lowest likelihood of occurring in the foreseeable future. The anticipated changes, under Scenario Four, for each ecotype stressors important to Dry Forests are given in [Table 7](#).

Conclusion

In summary, the conservation efforts by Federal, State, private, and multiple agency partnerships have been beneficial in helping to conserve and protect the remaining dry forests in Hawai'i. The restoration of dry forests cannot be accomplished solely on Federal lands because their range occurs primarily on non-Federal lands. To achieve restoration of these non-Federal dry forests requires cooperative conservation efforts on private and State lands. However, increasing funding sources remains a high priority, to accomplish the goals of expanding and actively managing the remaining dry forests.

The primary stressors to dry forests include habitat destruction and modification by invasive ungulates, competition with invasive species, natural disasters (hurricanes), fire, drought, agriculture and urban development, and climate change. These stressors, as described in more detail above, are serious and ongoing, act in concert with other stressors to dry forests, and are expected to continue or increase in magnitude and intensity into the future without effective management actions to control or eradicate them. In addition, the combined effects of ungulate, rodent, and invertebrate predation on dry forests suggests the need for immediate implementation of restoration and conservation methodologies. Without active management, dry forests will continue to be degraded and destroyed.

Finally, the condition of dry forests in the foreseeable future favors Scenario One, which has the highest likelihood of occurring in the foreseeable future relative to the other scenarios. Under Scenario One there is no change in the implementation of the conservation management parameters (CMPs). Scenario Two is based on a slight increase in the implementation of the CMPs, which marginally improves conservation management. Thus Scenario Two is expected to have the second highest likelihood of occurring into the foreseeable future, being slightly less likely than Scenario One. Scenario Three is based on a slight to moderate decrease in conservation actions in the CMPs which substantially decreases conservation management. Because there is a decrease in the implementation of the CMPs, Scenario Three would severely degrade and fragment native dry forest eco-types and result in reduced resiliency, redundancy, and representation. In Scenario Four, the substantial improvements in restoration for native dry forest eco-types would result in increased resiliency, redundancy, and representation. However, this scenario and Scenario Three have the lowest likelihood of occurring in the foreseeable future.

Overall, the CMPs are critical factors that drive the direction and magnitude of natural resource conservation and determine the foreseeable future scenarios. Any increase in the implementation of the CMPs will result in the greatest conservation returns for native dry forest (Scenario's Two and Four). Conversely, any decrease in the implementation of the CMPs will result in the least conservation returns for native dry forest (Scenario's One and Three). Thus, realistic expectations of the implementation of the CMPs were considered when determining the likelihood of occurrence for each scenario in the foreseeable future.

Abstract

Forest description, historic and current status, stressors, conservation efforts, and projection of potential future scenarios are analyzed for quality and quantity of wet forests across the Hawaiian islands. The wet forest ecosystem occurs on the windward sides of all the main Hawaiian islands except Ni'ihau and Kaho'olawe. Hawaiian islands wet forest is comprised of three native-dominated and one introduced plant communities: lowland rainforest, montane rainforest, montane cloud forest, and managed tree plantation. Stressors of wet forests include invasive plant and animal species, plant diseases and increased tropical cyclones from climate change. The keystone species of wet forests in Hawai'i is 'ōhi'a (*Metrosideros polymorpha*). 'Ōhi'a colonize new lava flows in the form of cohorts. In the later part of the wet forests lifecycle, the 'ōhi'a canopy breaks down in synchrony, a natural forest regeneration phenomenon known as *ōhi'a dieback*. Recently 'ōhi'a has experienced widespread mortality on the island of Hawai'i as a result of two novel species of the fungal genus *Ceratocystis*. This phenomenon is referred to as rapid 'ōhi'a death (ROD) and has had significant impacts on lowland rainforests. Once the canopy is opened either from 'ōhi'a dieback or ROD, invasive plants have greater potential to become established and disrupt the natural succession back to closed 'ōhi'a forest. Analysis under various "best" and "worst" case future scenarios show the continued decline of lowland rainforest except under the best case scenario of an increase in quantity and quality of rainforest compared to current conditions. Substantial improvements to laws, biosecurity, and implementation of intensively managed, fenced conservation areas are required to conserve this forest type in the future. Montane rainforest and montane cloud forest fair better under the future scenarios but are still vulnerable to decline if existing management actions are not maintained. Managed tree plantations are expected to increase as the human population increases.

Hawaiian Islands Wet Forest Description

Defining Hawaiian Wet Forest

A forest is a plant community characterized by vegetation dominated by trees (woody plants) generally 5–35 m in height, and often including a canopy, subcanopy, shrub, and an herbaceous layer (composed of nonwoody plants). The forest canopy is dense with 60–100% cover. The classification of Hawaiian wet forest is based on elevation, moisture, and physiognomy (look, aspect, or appearance). Physiognomic classes of wet forest are based on percentage cover of the dominant plant life-form in the uppermost vegetation layer. Those classified as “wet forest” have more than 2,500 mm annual rainfall and >25% cover in trees (Gagné and Cuddihy, 1999). Hawai'i wet forest include lowland rainforest, montane rainforest, and montane cloud forest.

Geology

Substrates for Hawai'i wet forest vary from very weathered soils on older islands to rocky substrates on recent lava flows on younger islands. There are two broad classes of soil substrates formed from basalt lava which support wet forests: undeveloped or geomorphologically recent soil substrates found on Hawai'i and Maui and well developed soils in humid climates. Within each of these classes there are a large number described soil types (Mueller-Dombois and Fosberg, 1998). Soils vary throughout the island chain, from gray acidic clays on older islands to thin organic mucks over lava flows and ash beds on Hawai'i.

Vegetation structure, composition, and subunits

Wet forests can be very tall exceeding 15 m but also shorter and scrubby in nature. Rainfall and persistent cloud cover is sufficient to support lush growth of vegetation comprised of many types of plant forms including lianas (long-stemmed, woody vines that are rooted in the soil), mosses, lichens, and ferns. Distinguishing characteristics among the different types of wet forest or subunits include elevation, precipitation, presence of clouds, vegetative structure, and plant communities. Wet forests contain discrete patches and mosaics of plant communities which occur across the landscape with spatial variation.

Lowland rainforest

Lowland rainforest occurs from 100 to 1,200 m elevation on all of the main islands except Ni'ihau and Kaho'olawe. Lowland rainforests typically have at least two tree layers, an upper one composed of *Meterosideros polymorpha* ('ōhi'a) alone or mixed with a codominant tree species such as *Cheiodendron* spp. ('olapa) or *Antidesma platyphyllum* (hame) and an understory of diverse lower-statured tree species including tree ferns—*Cibotium* spp. (hapu'u). Lowland rainforests are also home to lianas such as *Freycinetia arborea* ('ie'ie) and the ground is usually covered with mosses, sedges and a diverse array of fern species (Cuddihy, 1989; Gagné and Cuddihy, 1999).

Montane rainforest

Montane rainforest is found on the islands of Hawai'i, Maui, Moloka'i, Lāna'i, O'ahu, and Kaua'i between 823 and 2,200 m elevation. The boundary between the lowland and montane rainforests is not generally agreed upon by all botanists and ecologists, and it may be variable on the different islands. At lower elevations on the island of Hawai'i, montane rainforests merge with lowland rainforest. At upper elevations on Hawai'i and Maui, they quickly grade into mesic forests. The dominant tree species of montane rainforests is most often 'ōhi'a. A distinct type of forest with tall *Acacia koa* (koa) and 'ōhi'a occurs in areas with deep soil above the elevations of 900–1,200 m. Montane rainforests are multilayered, below the canopy of 'ōhi'a (or koa and 'ōhi'a) is a layer of diverse lower-statured trees in which no one species is dominant. Epiphytic mosses, liverworts, lichens, ferns and hapu'u are abundant on tree trunks and fallen logs. Fallen logs serve as nurse logs for seedling germination of wet forest species. On the island of Hawai'i a layer composed almost entirely of hapu'u is present, this occurs on other islands as well but to a lesser extent. As with lowland rainforest the ground cover consists of mosses, sedges and a diverse array of fern species (Cuddihy, 1989; Gagné and Cuddihy, 1999).

Montane cloud forest

Montane cloud forests occur between 750 and 1,830 m elevation on all the main Hawaiian islands except for Ni'ihau and Kaho'olawe. Hawaiian montane cloud forests are forests which receive a substantial amount of additional precipitation from fog drip on a regular basis. The division between montane rainforest and montane cloud forest can be hard to define as there is no exact qualitative or quantitative criteria to separate them. Medeiros et al. (1993) describes cloud forests on Moloka'i and Lāna'i in the same zone as others describe montane rainforest. Juvik and Nullet (1993) describe three zones of wet montane cloud forest and a fourth zone which is considered dry montane cloud forest. Wet montane cloud forests which face northeast trade winds on exposed mountain ridges and peaks consist of dwarf elfin forests with abundant mossy epiphytes. Wet montane cloud forests which occur on geologically young volcanic mountains at Haleakalā, Maui and Mauna Kea and Mauna Loa, Hawai'i are taller in stature and do not have a huge biomass of mossy epiphytes. The dominant tree species of montane cloud forests are 'ōhi'a and 'olapa. Koa is a codominant species in the taller stature montane cloud forests on young volcanic islands. Montane cloud forests are multilayered, species rich and host a diverse array of over 30 species of trees, 30 species of shrubs, and more than 60 species of ferns (Mueller-Dombois and Fosberg, 1998).

Sustainability

Wet forests need volcanic substrates, nutrient availability, light and to be situated high enough on the windward sides of the main islands to intercept moisture-laden trade winds for adequate rainfall ($> 2,500$ mm) to develop and sustain themselves (Gagné and Cuddihy, 1999). Adequate distribution across the landscape of wet forest contributes to its ability to perpetuate after a catastrophic event in one area by having a redundant or similar forest in another area.

Hawaiian wet forests start on new lava flows. Plants, lichens and mosses colonize in 1–2 years, and 'ōhi'a in 4 years (Smathers and Mueller-Dombois, 1972). Plant growth leads to leaf litter which provides organic matter to aid in the further development of the forest. The most common native plant in wet forests other than 'ōhi'a is a fern known as uluhe (*Dicranopteris linearis*). Uluhe forms dense mats which can be impenetrable, 'ōhi'a trees and other plants will eventually cover over and shade out uluhe and form a forest or re-form one. Haup'u, another dominant species of wet forests, are shade tolerant and able to colonize the understory of closed canopy mature 'ōhi'a forests. Haup'u cover declines after 3,000 years to be replaced by woody plants. In the later part of the wet forests lifecycle, the 'ōhi'a the canopy guild breaks down often in synchrony, a natural forest regeneration phenomenon known as 'ōhi'a dieback. The trigger is hypothesized to be climatic in nature. Five types of dieback are recognized and vary by substrate; dryland dieback, wetland dieback, displacement dieback and gap and bog formation dieback. The rainforest develops from young 'ōhi'a forests to mature diverse forests with inclusions of bog and stream ecosystems as it progresses through the stages of dieback (Mueller-Dombois and Boehmer, 2013).

Many of the relationships between plants, and their environment are reciprocal: rain, temperature, humidity, soil fertility influence plant growth, while plants affect microclimate and soil moisture, structure, acidity, and fertility. Mineral nutrients, such as nitrogen and phosphorus, cycle between the living and nonliving compartments of the forest. When Hawaiian wet forests are younger nutrients are rock-derived. As they age and the nutrients are leached and weathered away from high rainfall, nutrients are supplied to the forest by the atmosphere via dust from the deserts of central Asia. The atmosphere becomes the dominant source of all major biological nutrients apart from phosphorus in less than 100,000 years. Phosphorus is still the primary limiting factor for biological activity in older wet forests since the weathering source of phosphorus is depleted but also because atmospheric inputs of phosphorus are very low (Chadwick et al., 1999).

Biodiversity

Biodiversity is high in lowland rainforests, specialized plants, and animals occur there, such as tree snails (e.g., *Achatinella* and *Partulina* spp.) and endemic *Cyrtandra* spp. Biodiversity is moderate to high in montane rainforests and montane cloud forests. Specialized plants and animals which occur there include predatory caterpillars (*Eupithecia*) and lobeliads (Campanulaceae). The montane wet system is important habitat for forest birds (Hawaiian honeycreepers, thrushes, and flycatchers) and seabirds (Newell's shearwater and Hawaiian petrel) (The Nature Conservancy, 2006).

Cultural Significance

In ancient Hawai'i, lowland rainforests were a source of native plants used for fiber, weaving, clothing, medicines, and wood. This zone is referred to as *wao kanaka*, the realm of man. Montane rainforests and montane cloud forests were not for casual visitation as they were remote and difficult to access and considered the realm of Hawaiian gods or *wao akua*. Only priests and medicine men ventured into these forests for healing herbs or to collect forest birds for feather work worn by the ruling chiefs (HDLNR, 2003; Pratt and Gon, 1998).

Montane rainforests are considered sacred for the Hawaiian people as they are the primary sources of the island's freshwater. The montane rainforest is highly efficient at capturing and retaining water. The wet forest captures rainfall through the multiple layers of canopy, subcanopy, shrub, and an herbaceous layer which includes mosses and ferns. These layers and the leaf litter slow the rainfall down and act like a giant sponge, absorbing water and allowing it to drip slowly underground and into streams and aquifers. The forest can also pull moisture from passing clouds (The Nature Conservancy, 2006). Wetforests continue to see to the practical and spiritual needs of the people of Hawai'i.

Pre-Human Condition

Before the modern era, wet forests occurred on windward (northeastern) slopes above the coastal zone on the main Hawaiian islands (except for Ni'ihau and Kaho'olawe) and extended to the summits of Kaua'i, the Wai'anae Range of O'ahu and eastern Moloka'i, as well as the windward slopes of Maui and Hawai'i, where wet forest extended well above 1,650 m elevation, and included a narrow band on the Kona side of the island of Hawai'i (Figs. 1–4). The Nature Conservancy (2006) estimates the total prehuman extent of wet forest to be 455,833 ha.

Fig. 1 Map of historical and current extent of wet forests on the island of Hawai'i (Reeves and Amidon, 2018).

Prior to the arrival of the Polynesians to the main Hawaiian islands the vegetation cover may be inferred from existing vegetation, remnants in disturbed areas, patterns of climate and substrates, and a few fossilized remains (Cuddihy and Stone, 1990). Table 1 below lists plants that were found in prehuman times in wet forests by subunit type.

Lowland rainforest is thought to have been the predominant original vegetation of the windward lowlands on the larger main islands (Cuddihy and Stone, 1990). In prehuman times, a lowland rainforest dominated by *Acacia koa* (koa) was probably widespread below 1,000 m on the larger islands in windward areas with deep soils. A clear picture of prehuman vegetation in montane rainforests is complicated by the extreme disturbance the lowlands have suffered. However relatively intact high-elevation montane rainforest currently cover large expanses in the same locations as they did in prehuman times. Pollen samples indicate similar dominant species in prehuman times that occur at present in montane rainforests and montane cloud forests including, hapu'u, 'ōhi'a and 'olapa (Cuddihy and Stone, 1990).

Pre-human wet forest resilience

The wet forest system was redundant across multiple islands, distributed over a broad geography, and able to withstand catastrophic events. During the prehuman period, wet forests were resilient due to the large extent, diversity of species and ability of species to

Table 1 Plant species found in Hawaii wet forest in pre-human times by subunit (Gagné and Cuddihy, 1999; Landfire, 2016; Cuddihy, 1989).

Wet forest subunits	Characteristic plants
Lowland rainforest	<i>Acacia koa</i> , <i>Adenophorus</i> spp., <i>Alyxia stellata</i> , <i>Antidesma platyphyllum</i> , <i>Astelia menziesiana</i> , <i>Bobea elatior</i> , <i>Broussaisia arguta</i> , <i>Cheirodendron</i> spp., <i>Cibotium</i> spp., <i>Coprosma</i> spp., <i>Cyrtandra</i> spp., <i>Dicranopteris linearis</i> , <i>Diospyros sandwicensis</i> , <i>Diplopterygium pinnatum</i> , <i>Elaphoglossum</i> spp., <i>Freycinetia arborea</i> , <i>Hedyotis</i> spp., <i>Huperzia</i> spp., <i>Ilex anomala</i> , <i>Korthalsella</i> spp., <i>Leptecophylla tameiameiaie</i> , <i>Machaerina</i> spp., <i>Melicope</i> spp., <i>Metrosideros polymorpha</i> , <i>Myrsine</i> spp., <i>Peperomia</i> spp., <i>Perrottetia sandwicensis</i> , <i>Pipturus</i> spp., <i>Pittosporum</i> spp., <i>Polyscias</i> spp., <i>Pritchardia</i> spp., <i>Psychotria</i> spp., <i>Sadleria</i> spp., <i>Smilax melastomifolia</i> , <i>Sticherus owhyensis</i> , <i>Urera glabra</i> , <i>Vaccinium</i> spp.
Montane rainforest	<i>Acacia koa</i> , <i>Adenophorus</i> spp., <i>Alyxia stellata</i> , <i>Anoectochilus sandwicensis</i> , <i>Astelia</i> spp., <i>Athyrium</i> spp., <i>Broussaisia arguta</i> , <i>Bobea brevipes</i> , <i>Carex alligata</i> , <i>Cheirodendron</i> spp., <i>Cibotium</i> spp., <i>Clermontia</i> spp., <i>Coprosma</i> spp., <i>Cyrtandra</i> spp., <i>Cyanea</i> spp., <i>Dicranopteris linearis</i> , <i>Diplopterygium pinnatum</i> , <i>Dubautia</i> spp., <i>Elaphoglossum</i> spp., <i>Eurya sandwicensis</i> , <i>Hedyotis</i> spp., <i>Huperzia</i> spp., <i>Ilex anomala</i> , <i>Korthalsella</i> spp., <i>Leptecophylla tameiameiaie</i> , <i>Lobelia</i> spp., <i>Machaerina</i> spp., <i>Melicope</i> spp., <i>Metrosideros polymorpha</i> , <i>Myrsine</i> spp., <i>Peperomia</i> spp., <i>Perrottetia sandwicensis</i> , <i>Pittosporum</i> spp., <i>Polyscias</i> spp., <i>Pritchardia</i> spp., <i>Psychotria</i> spp., <i>Rubus hawaiiensis</i> , <i>Sadleria</i> spp., <i>Scaevola</i> spp., <i>Smilax melastomifolia</i> , <i>Stenogyne</i> spp., <i>Vaccinium</i> spp.
Montane cloud forest	<i>Acacia koa</i> , <i>Adenophorus</i> spp., <i>Alyxia stellata</i> , <i>Anoectochilus sandwicensis</i> , <i>Astelia</i> spp., <i>Broussaisia arguta</i> , <i>Cheirodendron</i> spp., <i>Cibotium</i> spp., <i>Clermontia</i> spp., <i>Coprosma</i> spp., <i>Cyrtandra</i> spp., <i>Cyanea</i> spp., <i>Dubautia</i> spp., <i>Dryopteris</i> spp., <i>Elaphoglossum</i> spp., <i>Huperzia</i> spp., <i>Ilex anomala</i> , <i>Korthalsella</i> spp., <i>Leptecophylla tameiameiaie</i> , <i>Lobelia</i> spp., <i>Machaerina</i> spp., <i>Melicope</i> spp., <i>Metrosideros polymorpha</i> , <i>Myrsine</i> spp., <i>Peperomia</i> spp., <i>Pittosporum</i> spp., <i>Phyllostegia</i> spp., <i>Sadleria</i> spp., <i>Smilax melastomifolia</i> , <i>Stenogyne</i> spp., <i>Trematolobelia</i> spp., <i>Vaccinium</i> spp.

recolonize after stochastic events such as landslides, tropical cyclones, lava flows, and fires. When new lava flowed on older rainforests, the forest began the process of regeneration. Islands of remnant vegetation separated by new lava flows were formed. These remnant islands of vegetation are known as kipuka, the seeds and spores from kipuka colonize new lava flows. Older landscapes subjected to fires, tropical cyclones or landslides were recolonized by native plant species in neighboring valleys and watersheds. Uluhe colonized areas which were denuded, 'ōhi'a trees and other plants eventually cover and over shade uluhe and form/reform the forest (Carlquist, 1980).

Representation, the number or percent of ecological settings across the range, was high in wet forests. Each subunit contained riparian areas, natural clearings, wetlands and bogs of mosses, sedges, grasses, and shrubs. These inclusions were common and they supported a variety of species, some of which are specific to a subhabitat type (e.g., wetland or bog obligate species). During prehuman times species diversity and endemism was high in each subunit of wet forest (The Nature Conservancy, 2006). High biodiversity increases the resiliency and representation of wet forests.

Current Condition

Current extent/range

The extent of Hawaiian islands wet forest today is largely similar across all islands as the prehuman condition, except for substantial loss of lowland rainforest on the islands of O'ahu and Kaua'i (Figs. 1–4). There are 373,764 ha of wet forest (all subunits combined) in the Hawaiian islands with 65% on the island of Hawai'i (Fig. 5). Seventy-eight percent (235,819 ha) is native species dominated (> 50% native species), the remaining portion of wet forest is nonnative species dominated (> 50% invasive species) (Fig. 6). There are nine vegetation classes of wet forest based on canopy height and cover and dominant tree species (Fig. 7). They are closed hala (*Pandanus tectorius*), closed koa-ōhi'a forest, closed 'ōhi'a wet forest, low stature 'ōhi'a wet forest, mixed native nonnative wet forest, nonnative wet forest, open koa-ōhi'a wet forest, open 'ōhi'a wet forest and plantation forest. Dominant native species are mostly the same in lowland rainforest, montane rainforest and montane cloud forests as in prehuman times (Table 1). Nonnative species are listed below in the subunit descriptions. A fourth subunit of wet forest, Hawai'i managed tree plantation, is also described.

Lowland rainforest

Lowland rainforest became invaded during the 20th century in many areas by ecosystem altering nonnative plants including but not limited to: *Psidium cattleianum* (strawberry guava), *Albizia moluccana* (Albizia), *Melastoma candidum*, *Clidemia hirta* (Coster's curse), *Rubus* spp., *Aleurites moluccana* (kukui nut tree) and *Syzygium malaccense* (mountain apple). Though lowland rainforest is still widespread throughout Hawai'i, invasive trees have significantly impaired the system's ability to perpetuate itself. In fact many areas where native lowland rainforest used to occur are completely dominated by alien species. Other dominant alien species in these forests include but are not limited to: *Mangifera indica* (mango), *Psidium guajava* (common guava), *Syzygium cumini* (Java plum), *S. jambos* (rose apple) and *Phyllostachys nigra* (bamboo) (Gagné and Cuddihy, 1999).

Montane rainforest and montane cloud forest

Hawai'i montane rainforest and montane cloud forest were minimally affected prior to western contact, largely because these upper elevation wet forests are remote and difficult to access. Hawaiians ventured primarily to lower elevation forests for koa and other forest products (Cuddihy and Stone, 1990). Early in the 18th century with the introduction of cattle and more efficient logging of koa and 'ōhi'a, some montane cloud forests on Maui, Moloka'i, and Hawai'i were converted to pasture lands, a process that was accelerated by the introduction of nonnative forage grasses (Cuddihy and Stone, 1990; Pratt and Jacob, 2009). In addition to nonnative grasses, other nonnative species which invade montane wet and montane cloud forests include Himalayan ginger (*Hedychium gardnerianum*), Australian tree fern (*Cyathea cooperi*), and mules foot fern (*Angiopteris evecta*).

Hawai'i managed tree plantation

During the early 20th century large private forest reserves (protected areas) were created in response to the damage caused to native forests from grazing, logging, and feral animals. Mostly nonnative trees were planted above sugar plantations at Lihu'e, Kaua'i (4,050 ha) and Pahala, Hawai'i (20,240 ha), and on Maui and O'ahu for watershed protection (Cuddihy and Stone, 1990). Tree plantings for forest restoration consisted of introduced, fast-growing tropical species such as, *Eucalyptus globulus*, *E. robusta* (swamp mahogany), *Melaleuca quinquenervia* (paperbark), *Ficus* spp. (banyan) among others. Native species and commercially valuable timber were avoided so that future generations would not be tempted to harvest the trees that would result in damage to the watershed (Cuddihy and Stone, 1990). The emphasis on forest reserves as protected watersheds began to change during the 1940s and 1950s. Experimental planting of introduced trees accelerated, and large-scale plantings of timber species began in forest reserves (Hosmer, 1959). Currently, managed tree plantations are of commercially valuable trees harvested for lumber and fuel. Introduced trees planted for lumber and fuel include, *Araucaria columnaris*, *Araucaria heterophylla*, *Eucalyptus* spp., *Pinus elliottii*, *Pinus radiata*, and *Sequoia sempervirens*. Plantations are often at the lower elevation edge of current forest reserves (Landfire, 2016). There are 10,645 ha of wet forest managed tree plantations (see Table 2). Commercial koa forestry on deforested lands emerged in recent decades to supply demand for this valuable hardwood (Skolmen and Fujii, 1980; Baker et al., 2009). Koa silviculture is practiced on old pasturelands in wet areas.

Wet forest land ownership

Fifty-eight percent (176,943 ha) of Hawaiian islands wet forest is owned by Federal, State, local and Hawaiian homelands government, except for island of Lāna'i, which is entirely privately owned (Fig. 8). Lāna'i contains 1,291 ha of wet forest. On the island of Hawai'i there are 521,900 ha of conservation district lands, that include large areas of wet forest. Housing development and intensive agriculture (planting of field crops) are not permitted on lands zoned for conservation (County of Hawai'i, 1970).

Fig. 5 Wet forest area summary (Reeves and Amidon, 2018).

Stressors

The health and distribution of Hawaiian islands wet forest is affected by natural and nonnative processes and agents. These stressors include introduced ungulates, plants, predators (rats, cats, and mongoose), herbivores (slugs, rodents, and insects), and plant disease. Fire, drought, natural disasters, climate change, agriculture, and urban development also threaten and degrade wet forests. The most significant stressors are discussed below.

Invasive ungulates

Hawaiian wet forests are currently threatened by the destruction or degradation of habitat due to invasive ungulates, including pigs, goats, deer, and cattle. The mild climate of the islands, combined with the lack of competitors or predators, led to the successful establishment of large populations of these invasive mammals, to the detriment of native Hawaiian species and ecosystems. The wet forests are exposed to both direct and indirect negative impacts of invasive ungulates. The effects of ungulates include the destruction of vegetative cover; trampling of plants and seedlings; direct consumption of native vegetation; soil disturbance; dispersal of invasive plant seeds on hooves and coats, and through the spread of seeds in feces; and creation of open disturbed areas conducive to further invasion by invasive plant species. All of these impacts can lead to the subsequent conversion of a native plant community to one dominated by invasive species (Nogueira-Filho et al., 2009). In addition to these direct effects, because ungulates inhabit terrain that is often steep and remote, foraging and trampling contributes to severe erosion of watersheds and degradation of streams (Cuddihy and Stone, 1990). As early as 1900, there was increasing concern expressed about the integrity of island watersheds due to effects of ungulates and other factors, leading to the establishment of a professional forestry program emphasizing soil and water conservation.

Invasive plants

Invasive plants adversely affect microhabitat in the forest by modifying availability of light and nutrient cycling processes, and by altering soil-water regimes (Smith, 1985). Some invasive plants may release chemicals that inhibit growth of other plants. These competitive advantages allow invasive plants to convert native-dominated plant communities to nonnative plant communities. Native vegetation on all of the main Hawaiian Islands has undergone extreme alteration because of past and present land

Fig. 6 Wet forest habitat quality summary (Reeves and Amidon, 2018).

management practices, including ranching, the deliberate introduction of nonnative plants and animals, and agricultural development (Cuddihy and Stone, 1990). The original native flora of Hawai'i (species that were present before humans arrived) consisted of about 1,000 taxa, 89% of which are endemic (species that occur only in the Hawaiian Islands). Over 800 plant taxa have been introduced from elsewhere, and nearly 100 of these have become pests (e.g., injurious plants) in Hawai'i (Smith, 1985; Gagné and Cuddihy, 1999). A smaller subset of species have attributes which degrade native wet forest ecosystems. These relatively few species, however, are capable of serious and irreversible damage.

Although 'ōhi'a dieback is considered a natural forest regeneration phenomenon, now widespread invasive plant species such as strawberry guava and albizia, are having negative impacts on the natural regeneration of the native Hawaiian wet forest following 'ōhi'a dieback occurrences. Strawberry guava spreads clonally and by seeds, it forms dense thickets which do not allow any other species to grow. Albizia is a nitrogen-fixing tree which grows very fast, it overgrows the otherwise dominant 'ōhi'a. Wherever this overgrowth occurs 'ōhi'a dies from lack of light under the canopy of the trees (Mueller-Dombois, 2008). Feral ungulates exacerbate the spread of strawberry guava and other nonnative weeds and negatively impact the regeneration of native 'ōhi'a lowland rainforests (Murphy et al., 2014; Mueller-Dombois and Boehmer, 2013).

Plant disease

The primary plant disease that impacts wet forests are two species of the fungal genus *Ceratocystis* which cause mortality in 'ōhi'a, referred to as rapid 'ōhi'a death (ROD). 'Ōhi'a is Hawai'i's most common and widespread native tree, occurring from sea level to 8,200 ft (2,500 m) elevation and is often a dominant species in lowland, montane wet, and montane cloud forest. It is an ecologically important species that defines native forest succession and ecosystem function, provides habitat to many native species, and is also culturally significant (Keith et al., 2015).

Rapid 'ōhi'a death was identified in 2012 on the island of Hawai'i and discovered in 2018 on the island of Kaua'i. The disease causes browning in the crowns of 'ōhi'a trees and ultimately leads to mortality. By the end of 2014, it was reported that approximately 2,428 ha of forest stands from Kalapana to Hilo showed greater than 50% mortality (Friday et al., 2015). By 2017 approximately 30,351 ha showed symptoms of ROD, including areas in Kona where dry forest habitat occurs. Once a stand is infected, nearly 100% of the trees can succumb to the disease within 2–3 years. Humans are thought to be a primary vector of transmission by moving infected wood, or contaminated tools, gear, and vehicles from one location to another. In addition, research has

Fig. 7 Wet forest vegetation summary (Reeves and Amidon, 2018).

Table 2 Hawaii managed tree plantation wet forest extent by Island (Reeves and Amidon, 2018).

<i>Island</i>	<i>Acres/hectares of managed tree plantation</i>
Kaua'i	276/112
O'ahu	1156/468
Moloka'i	119/48
Hawai'i	24,753/10,017

identified a nonnative ambrosia beetle as another likely vector. The beetles bore into trees and create a fine dust, referred to as frass, that can be carried by the wind and enter 'ōhi'a through wounds (CTAHR, 2018). Stands which are affected by ROD in areas where invasive plants such as strawberry guava and albizia occur, as mentioned above regarding 'ōhi'a dieback, are not likely to recover to native species dominated forests.

Natural disasters

In addition to their direct effects on plants, tropical cyclones (tropical storms and hurricanes) exacerbate the impacts from other threats such as habitat modification and destruction by ungulates and competition with invasive plants. By destroying vegetation, tropical cyclones open the forest canopy, thus modifying the availability of light, and create disturbed areas conducive to invasion by invasive plants (Asner and Goldstien, 1997; Harrington et al., 1997). Two hurricanes (Iwa and Iniki respectively) struck Kaua'i in 1982 and 1992 causing much damage to the montane wet forest of the Alakai Wilderness Preserve. Several species of endangered honeycreepers have not been sighted since Hurricane Iniki in 1992 despite intensive bird surveys in formally occupied areas within the preserve (USFWS, 2006).

Climate change

The Hawaiian Islands Climate Vulnerability and Adaptation Synthesis evaluated wet forests as having overall moderate vulnerability to climate change with moderate-high sensitivity to climatic factors and disturbance regimes such as tropical cyclones,

Fig. 8 Wet forest land ownership summary (Reeves and Amidon, 2018).

drought, and fire (Gregg, 2018). Wet forests are sensitive to factors that alter moisture gradients. Alteration of moisture gradients may impact species composition and forest distribution and potentially reduce habitat extent. The synthesis predicts that wet forests in remote areas will remain relatively intact but lower elevation forests will become more degraded.

Conservation Efforts

Active conservation is conducted by Federal and State agencies, nonprofit organizations, and private landowners. In Table 3 below, existing conservation areas that contain wet forests are listed by island. Efforts by conservation organizations may include invasive plant and animal control, and native forest restoration. Invasive plant control includes the use of herbicides, hand tools, and in some instances, biocontrol methods to reduce the numbers and distribution of invasive plants in mesic forests. For example, the Brazilian scale (*Tectococcus ovatus*) has been introduced to control strawberry guava. Reintroduction of native plants is also used to control the spread of invasive plants. Ungulates are controlled through the use of exclusion fences, trapping, and hunting. Predator control for rats, mongoose and cats (via rodenticide and/or trapping) is occurring in wet forests which are important for forest-birds and seabirds (HDLNR, 2016).

Reserves

Twenty percent (10,769 ha) of wet forest in the state of Hawai'i is protected in reserves. Reserves that benefit wet forests are found throughout the state of Hawai'i and exist in national parks, national wildlife refuges, State natural area reserves, State forest reserves, and on private preserves. The State of Hawai'i's Forest Reserve System (FRS) from its inception represented a public-private partnership for the protection of upland forests needed to provide water requirements for lowland agriculture demands and use by surrounding communities (Cuddihy and Stone, 1990). There are 274,625 ha in the FRS on the islands of Kaua'i, O'ahu, Moloka'i, Maui, and Hawai'i, protecting large areas of Hawai'i wet forest (HDLNR, 2018). The State of Hawai'i's Natural Area Reserve System (NARS) was established to preserve and protect representative samples of Hawaiian biological ecosystems and geological formations. There are 21 natural area reserves that have been designated statewide (HDLNR, 2016). Several of these reserves contain

Table 3 Wet forest conservation areas in the Hawaiian Islands (HDLNR, 2018; Reeves and Amidon, 2018).

<i>Island</i>	<i>Wet forest subcategory</i>	<i>Name of reserve</i>	<i>Landowner</i>	<i>Number acres (hectares) protected</i>
Kaua'i	Lowland and montane wet	Hono O Nā Pali Natural Area Reserve	State	2286 (925)
Kaua'i	Montane wet	Alakai Wilderness Preserve	State	1953 (790)
Kaua'i	Lowland wet and montane wet	The Nature Conservancy-Wainiha Preserve	Private	5405 (2187)
Kaua'i	Lowland wet	National Tropical Botanical Garden-Limahuli Preserve	Private	459 (186)
Kaua'i	Lowland wet	Blue Hole, Lihue Koloa Forest Reserve	State	30 (12)
O'ahu	Lowland wet	Kaluanui Natural Area Reserve	State	367 (149)
O'ahu	Montane wet	Mt. Ka'ala Natural Area Reserve	State	224 (91)
Maui	Montane wet and montane cloud	Hanawi Natural Area Reserve	State	4820 (1951)
Maui	Montane wet	West Maui Natural Area Reserve	State	357 (144)
Maui	Montane wet and montane cloud	The Nature Conservancy-Waikamoi Preserve	Private	3496 (1415)
Maui	Lowland wet and montane wet	Haleakalā National Park	Federal	7388 (2990)
Moloka'i	Montane wet	Pu'u Ali'i Natural Area Reserve	State	858 (347)
Moloka'i	Montane wet and lowland wet	Oloku'i Natural Area Reserve	State	1284 (520)
Moloka'i	Montane wet	The Nature Conservancy-Pelekunu Preserve	Private	1639 (663)
Moloka'i	Montane wet	The Nature Conservancy—Kamakou Preserve	Private	1197 (484)
Hawai'i	Lowland and montane wet	Kahauale'a Natural Area Reserve	State	16,292 (6593)
Hawai'i	Lowland wet	Kipahoehe Natural Area Reserve	State	2800 (1133)
Hawai'i	Lowland and montane wet	Laupahoehoe State Natural Area Reserve	State	7968 (3225)
Hawai'i	Lowland and montane wet	Pu'u Maka'ala Natural Area Reserve	State	17,169 (6948)
Hawai'i	Montane wet	Kamehameha Schools-Kilauea Forest	Private	2955 (1196)
Hawai'i	Lowland and montane wet	Ka'ū Forest Reserve	State	12,000 (4856)
Hawai'i	Lowland and montane wet	The Nature Conservancy-Ka'ū	Private	3561 (1441)
Hawai'i	Lowland and Montane Wet	Kamehameha Schools Ka'ū Forest	Private	2883 (1167)
Hawai'i	Montane wet and montane cloud	Pu'u O 'Umi Natural Area Reserve	State	10,122 (4096)
Hawai'i	Lowland and montane wet	Hakalau National Wildlife Refuge	Federal	28,109 (11,376)
Hawai'i	Lowland and montane wet	Hawaii Volcanoes National Park	Federal	21,774 (8812)

wet forest habitat. The Hono O Nā Pali, Kaluanui, Mt. Ka'ala, Pu'u Ali'i, Oloku'i, Hanawi, West Maui, Kahauale'a, Kipahoehe, Laupahoehoe, Pu'u Maka'ala, and Pu'u O 'Umi Natrual Area Reserves contain large areas and excellent examples of lowland wet, montane wet and montane cloud forest. There are several other reserves throughout the state which benefit wet forests. The Nature Conservancy of Hawai'i has 11 preserves in the State of Hawai'i encompassing more than 16,187 ha, including 9,195 ha of wet forest. On Kaua'i, the State of Hawaii manages the Alaka'i Wilderness Preserve, portions of which are fenced to exclude invasive ungulates and invasive plant control efforts are ongoing. On Maui, large areas of native wet forest are fenced to exclude feral ungulates at Haleakalā National Park and The Nature Conservancy's, Waikamoi Preserve. On Moloka'i, The Nature Conservancy's, Pelekunu and Kamakou Preserves, are fenced and ungulates have been removed. On Hawai'i Island, large areas of wet forest are protected in Hawai'i Volcanoes National Park, the Hakalau Forest National Wildlife Refuge and in the The Nature Conservancy's Ka'ū Preserve. Ongoing invasive plant control is also occurring in many of these areas.

Watershed partnerships

Watershed partnerships are voluntary alliances of public and private landowners and water municipalities committed to protecting over 809,371 ha of the most important watershed lands in Hawai'i. Individual watershed partnerships have been established on five islands (Hawai'i, Maui, Moloka'i, O'ahu, and Kaua'i) to support statewide watershed protection needs (see Fig. 9 and Table 4). The first watershed partnership formed in 1991 (East Maui Watershed Partnership) and in 2003 on the 100th anniversary of Hawai'i's Forest Reserve System, Governor Linda Lingle signed a Memorandum of Understanding (MOU) with the watershed partnerships formally recognizing the states dedication to watershed protection and established the Hawai'i Association of Watershed Partnerships (HAWP) (HAWP, 2018). Typical management activities implemented by watershed partnerships which protect wet forests include landscape scale ungulate proof fencing, ungulate and invasive plant removal and rare species protection. Several partnerships manage large scale active restoration projects which plant native plants back into degraded areas. In addition to on the ground work, watershed partnerships play an important role in community outreach, education, and engagement.

Rain Follows the Forest Initiative

The State of Hawaii, HDLNR launched the "Rain Follows the Forest" or Hahai no ka ua i ka ululā'au Plan in November 2011. The goal of the plan is to double the amount of protected watershed area for the purpose of securing water supply by 2021. The plan recognizes that the most efficient way to secure island water supply is by protection of the source, montane rainforests.

Hawai'i Watershed Partnerships

Fig. 9 Map of the distribution of the Hawai'i Association of Watershed Partnerships. Adapted from Hawai'i Association of Watershed Partnerships [HAWP]. (2018). *Watershed Partnerships*. <http://hawp.org/>.

Table 4 Watershed Partnerships, number of partners, hectares managed, and wet forest protection in the Hawaiian Islands (HAWP, 2018).

Island	Watershed partnership	Number of partners	Total management area/wet forest Ha
Kaua'i	Kaua'i Watershed Alliance	11	58,276/4,088
O'ahu	Ko'olau Mountains Watershed Partnership	16	40,469/4,452
O'ahu	Wai'anae Mountains Watershed Partnership	8	18,963/405
Maui	East Maui Watershed Partnership	9	48,360/16,544
Maui	West Maui Mountains Watershed Partnership	13	19,150/8,824
Moloka'i	East Moloka'i Watershed Partnership	15	16,862/4,047
Hawai'i	Three Mountain Alliance	10	445,154/111,289
Hawai'i	Mauna Kea Watershed Alliance	8	103,700/11,376
Hawai'i	Kohala Watershed Partnership	11	29,947/2,428

Consequently several thousand acres of montane rainforests have been protected and several thousand additional acres are targeted for protection across the state, see Fig. 10 below. HDLNR works with watershed partnerships to implement the plan.

Laws and Biosecurity

Biosecurity

Control of introduction and spread of invasive species is critical to protect the integrity of wet forest ecosystems. Executive orders 11987 (1977), 13112 (1999), and 13751 (2016) direct federal and encourage other agencies, councils, and processes to coordinate efforts to prevent the spread of invasive species.

Watershed Priority Areas

Fig. 10 Rain Follows the Forest Initiative priority areas for protection (HDLNR, 2011).

Prevention and management of invasive species helps prevent the further incursion of invasive species into Hawai'i that can establish and outcompete native wet vegetation or destroy seedlings and regeneration, especially after disturbance events. Invasive species are a primary stressor for wet forest and therefore prevention and management across the State of Hawai'i is essential to protect the remaining wet forest.

The Hawai'i Invasive Species Council (HISC) is a State of Hawai'i body that provides funding and is responsible for the Hawai'i Interagency Biosecurity Plan that guides the state's biosecurity implementation and tracking Hawai'i's biosecurity comprises many components and is the work of multiple state, federal, and county agencies and partners. Although the Hawai'i Department of Agriculture (HDOA) is the only agency with a mandated biosecurity program, this biosecurity plan recognizes that HDOA is not alone in protecting Hawai'i's agriculture, environment, and people from the impacts of invasive species. Key players in Hawai'i's biosecurity include the Hawai'i HDLNR, Hawai'i Department of Health (DOH), and University of Hawai'i (UH).

Endangered Species Act

Wet forests in Hawai'i provide habitat for many endangered plant, insect, and forest bird species. The Endangered Species Act of 1973 (ESA) aims to provide a framework to conserve and protect endangered and threatened species and their habitats. As habitat loss is the primary threat to most imperiled species, the ESA allows the Fish and Wildlife Service (FWS) and National Marine Fisheries Service (NMFS) to designate specific areas as protected critical habitat zones. In 1978, Congress amended the law to make critical habitat designation a mandatory requirement for all threatened and endangered species. Twenty percent (80,980 ha) of wet forest habitat in the state of Hawai'i is designated as critical habitat for several endangered species including forest birds, plants, and invertebrates (Fig. 11). Section 4 of the ESA refers to the section of the act pertaining to the determination of threatened and endangered species, as well as the establishment of critical habitat. Critical habitat is the regulatory link between habitat protection and recovery goals, it requires the identification and protection of all lands, water and air necessary to recover endangered species. The need for individual and population growth including food, water, light, nutritional requirements, breeding sites, seed germination, seed dispersal, and lack of disturbances are all considered in determining critical habitat.

Fig. 11 Federally designated critical habitat on the main Hawaiian Islands composed of wet forest habitat (Reeves and Amidon, 2018).

Summary of Interactions of Stressors and Conservation Efforts

The extent of Hawai'i wet forest today is largely similar across all islands as the prehuman condition, except for substantial loss of lowland rainforest on the islands of O'ahu and Kaua'i. Loss of lowland rainforest is due to invasion by feral ungulates, invasive plants, agriculture and development. Effects of tropical cyclones before the introduction of invasive plants to Hawai'i were likely short lived, and areas damaged soon recolonized by native plants. With large areas of wet forest now partly invaded by invasive plants, tree canopy removal by tropical cyclones have been shown to accelerate the process of invasion. Loss and degradation of lowland rainforest results in decline in distribution and therefore decreases redundancy. Invasive plants and animals displace native species which decreases the quality and size and native lowland rainforests which decreases resiliency. Representation, the unique ecological features within the forest, is also decreased as invasive species out-compete native species which causes declines in species richness and genetic range.

Montane rainforests and cloud forests have been degraded but to a lesser extent than lowland rainforests. Montane rainforests and cloud forests still dominated by native species have shown to be more resilient to stressors as shown by the fact that intact native high-elevation wet forests are redundant in remote and central regions of all of the main islands. Representation is still high in montane rainforests and montane cloud forests, as these forests still contain riparian areas, natural clearings, wetlands and bogs of mosses, sedges, grasses, and shrubs. These forests have been the focus of conservation efforts through the watershed partnerships since the early 1990s and are receiving additional support from HDLNR's *Rain Follows the Forest Plan*. Conservation measures will need to be maintained into the future which can prove challenging with limited resources. Increased biosecurity measures could limit the spread of plant diseases such as ROD and prevent further introduction and spread of invasive species.

Hawaii managed tree plantations are expected to increase as the human population grows throughout the islands, increasing the demands for fuel and forest products, carbon storage, horticulture, and agriculture (coffee, fruit, nut orchards). **Table 5** summarizes the impacts of these interactions on the sustainability (resiliency, representation, and redundancy) of wet forest habitats.

Table 5 Summary of interactions of stressors and conservation efforts.

<i>Wet forest subunit</i>	<i>Redundancy</i>	<i>Resiliency</i>	<i>Representation</i>
Lowland rainforest	Decrease	Decrease	Decrease
Montane rainforest and montane cloud forest	Stable	Stable	Stable
Hawaii managed tree plantation	Increase	Increase	N/A

Future Scenarios

The condition of wet forests in the foreseeable future is based on potential changes in three conservation management parameters (CMPs). These conservation parameters capture the social and legal mechanisms under which natural resource conservation is carried out. The CMPs are as follows:

- (1) Conservation values: stakeholder involvement and public opinion determine the formulation, implementation, and funding of natural resource conservation within laws and development plans.
- (2) Laws and biosecurity: national, state, county, and city laws and regulations are the means by which natural resource conservation and biosecurity are supported and implemented (e.g., hunting regulations, Clean Water Act, Endangered Species Act, and local laws, etc.).
- (3) Development or conservation planning: national, state, county, city, and private development plans or conservation plans define specific actions that result in losses or gains in natural resource conservation and biosecurity (impacts are only realized at the time of implementation).

These conservation management parameters are critical factors that drive the direction and magnitude of natural resource conservation, and determine foreseeable future scenarios. The year 2035 is the extent of the “foreseeable future,” and is based on the projected divergence of IPCC Representative Concentration Pathway (RCP) climate change scenarios (van Vuuren et al., 2011; Miller, 2018).

The four foreseeable future scenarios considered in this assessment are:

Future Scenario One, Status Quo—the most likely foreseeable future; no change in natural resource conservation in the CMPs, so the current rate of change in land cover continues throughout the foreseeable future.

Future Scenario Two—a slight increase in natural resource conservation in the CMPs marginally improves conservation management.

Future Scenario Three—a slight to moderate decrease in conservation actions in the CMPs substantially decreases conservation management.

Future Scenario Four—a moderate to large increase in conservation actions in the CMPs substantially improves conservation management.

The future condition of wet forest in Scenario One, the status quo, was characterized from an assessment of change over time in wet forest land cover obtained from existing land cover maps (Amidon and Reeves, 2018). Based on these land cover maps, an annual rate of change for wet forest was estimated, and a projected change (in hectares) was calculated for the year 2035. The resulting information on changes in land cover by 2035, as derived from existing land cover change estimates, is the extent of the wet forest that is expected in the foreseeable future under Scenario One, the status quo, where conservation efforts remain unchanged and the current rate of change in land cover is also unchanged.

The future conditions of wet forest for Scenarios Two, Three, and Four cannot be quantitatively (hectares) estimated. However, the Scenario One estimate can provide a “baseline” for a qualitative characterization of changes in the future condition of wet forest under Scenarios Two, Three, and Four.

Changes in human population are captured only by the changes in the “developed” land cover footprint derived from land cover map analysis (Amidon and Reeves, 2018). Impacts from other sources of human activities or human-caused stressors (e.g., plant and animal diseases, wildfires, invasive species, etc.) are not well characterized in the land cover changes, but significantly contribute to increases in the land cover area dominated by nonnative vegetation.

Also, note that island-wide implementation of the CMPs is unlikely to have a significant effect on climate-related stressors (temperature, precipitation, and severe weather) resulting from global warming by 2035. This lack of CMP climate effects is due to the global lag in climate response to changes in greenhouse gas emissions which occurs on the order of centuries rather than years (Solomon et al., 2009; Gillett et al., 2011; Jevrejeva et al., 2012). Evidence of climate effects is also confounded by the large annual variation in the Pacific Islands climate parameters, which is much greater than projected climate change by 2035. Although impacts from climate-related stressors do not change across the four scenarios, they were included in this analysis because of their overall magnitude of potential importance to future habitat viability.

Future Scenario One—Status Quo: Scenario One is considered the most likely future scenario, and serves as a “baseline” for comparing among the four future scenarios. There is no change in the implementation of the three CMPs between 2018 and 2035. A continuing current rate of change in land cover throughout this foreseeable future results in a slow but continuous change in wet forest as described below.

Scenario One will result in small increases of stressors. All wet forests have the potential for degradation under this scenario at varying extents. Lowland rainforest are expected to continue to decline in redundancy, resilience, and representation due to development, agriculture and invasive species. Montane rainforests and montane cloud forests will be less impacted than lowland rainforests by small increases of stressors since much of the montane wet forests are in relatively good condition. Montane rainforests and montane cloud forests which are being managed for ungulates and nonnative plants will continue to be sustainable. Hawaii managed tree plantation will continue to increase as the human population increases.

Future Scenario Two: there is a slight increase in the CMPs that marginally improves conservation management.

Under Scenario Two, lowland rainforests are expected to continue to decline. Removing the pressures of development will provide some benefit but invasive species will continue to degrade lowland wet forests. A small increase in CMPs will provide some benefit to lowland wet forests but not enough to stem the spread of existing invasive species. Active restoration, removal of invasive species and reintroduction of native species, is required to preserve remaining lowland rainforests. These activities require a substantial amount of resources and commitment from government agencies and local communities. Scenario Two will have little impact on montane rainforest and montane cloud forests as these areas are in remote and inaccessible areas and are not suitable for development. As in Scenario One, montane rainforests and montane cloud forests which are being managed for ungulates and nonnative plants will continue to be sustainable. Hawai'i managed tree plantation will continue to increase but at a slower rate due to limited development.

Future Scenario Three: there is a small to moderate decrease in conservation actions in the CMPs that substantially decreases conservation management.

All natural resource management actions in the CMPs are set aside in deference to land use for economic development. With extensive localized management, some native species may persist in park-like settings or in areas where land development is not possible.

Under Scenario Three, lowland rainforests are expected decline at a significantly faster rate. Current areas of native lowland rainforest may become developed or converted to agriculture and managed tree plantations. Setting aside natural resource management actions and CMPs will increase the spread of invasive species in lowland wet forests. Scenario Three would negatively impact montane rainforests and montane cloud forests as current management would likely be abandoned. Ungulates and invasive plants will degrade these forests. Hawaii managed tree plantation will significantly increase to fuel economic development.

Future Scenario Four: there is a moderate to large increase in conservation actions in the CMPs that substantially improves conservation management.

Under Scenario Four, lowland rainforests will increase. Current areas of native lowland forest will be prioritized for conservation. Increased support for control of invasive species and active restoration, planting native vegetation rather than only addressing stressors, will lead to an increase in native lowland wet forest. Montane rainforest and montane cloud forests will increase. Areas that are currently managed will continue to be managed ensuring sustainability of montane rainforests and montane cloud forests into the future. Additional montane rainforests and montane cloud forests that are not currently managed for invasive species will be fenced and ungulates and invasive plant species will be removed. Hawaii managed tree plantation will increase to meet the demands for forest and orchard products for the growing human population.

Conservation Implications

Under the most likely future scenario, lowland rainforest are expected to decrease in resiliency, redundancy, and representation. Alien species dominated lowland rainforests are predicted to increase. Substantial improvements to laws, biosecurity, and implementation of intensively managed, fenced conservation areas are required to conserve this forest type in the future. Montane rainforest and montane cloud forest fare better since they have been actively managed through various states, federal and private initiatives but are still vulnerable to decline if existing management actions are not maintained. Resiliency, redundancy and representation are expected to remain stable if management initiatives continue for montane rainforest and montane cloud forests. Managed tree plantations are expected to increase as the human population increases. [Table 6](#) summarizes the overall condition for wet forest under the future scenarios.

Table 6 Summary of overall condition for wet forest in the future scenarios.

<i>Wet forest subunit</i>	<i>Scenario 1: Status quo</i>	<i>Scenario 2: Slightly improved</i>	<i>Scenario 3: Substantially decreased</i>	<i>Scenario 4: Substantially improved</i>
Lowland rainforest	Decrease	Decrease	Significantly decrease	Increase
Montane rainforest	Stable	Stable	Decrease	Increase
Montane cloud forest	Stable	Stable	Decrease	Increase
Hawaii managed tree plantation	Increase	Slowly increase	Significantly increase	Increase

Abstract

This paper is an assessment of the Hawaiian Islands mesic forests, including the current status, stressors, and future viability. Mesic forests in Hawai'i generally receive between 1200 and 2500 millimeters (mm) of rainfall annually and are found on leeward and windward sides of the islands in lowland or in montane-subalpine zones (Cuddihy and Stone, 1990). These zones are differentiated by elevation and climate, which primarily dictate which species can exist in them (Gagne and Cuddihy, 1999). Historically, mesic forests in Hawai'i were located on all of the main Hawaiian Islands. These forests were distributed across the islands of O'ahu, Maui, Kaua'i, and Hawai'i, and to a lesser extent, on Moloka'i and Lāna'i. Currently, mesic forests are still found on all of the main Hawaiian Islands. However, the quality of these forests are largely composed of a mixture of native/nonnative vegetation. In addition to the native lowland and montane-subalpine mesic forests that characterized mesic forests historically, introduced mesic forests and managed tree plantations are now classified as mesic forests in the main Hawaiian Islands. Our assessment of mesic forest viability, defined as the likelihood of persistence over the long term, is based on the concepts of representation, redundancy, and resiliency. The main stressors to mesic forests are invasive ungulates, invasive plants, plant disease, invasive herbivores, wildfires, drought, natural disasters (i.e., hurricanes), and agriculture and human development. Ongoing conservation efforts are helping to protect mesic forests in Hawai'i. The conservation of mesic forests depends largely on combined efforts of State, Federal, multiagency organizations, nonprofit organizations, and the voluntary support of private landowners.

Introduction

The Hawaiian archipelago is the most isolated landmass in the world and is composed of eight large, "main" islands (Hawai'i, Maui, Lāna'i, Moloka'i, Kaho'olawe, O'ahu, Kaua'i, Nī'ihau), and 124 smaller islands, islets, atolls, and shoals. Nearly the entire land area is concentrated on the eight largest Hawaiian Islands (Wagner et al., 1999). The geography, geology, climate, hydrology, and descriptions of the islands in the Hawaiian archipelago are described in the chapter on Physical Geography of the Hawaiian Islands by Harrington in this work. We provide an overview of the Mesic Forest biome in the Hawaiian archipelago and describe the ecological factors that have influenced this biome over time and into the future.

Description

A forest is a plant community characterized by vegetation dominated by trees (woody plants) generally 5–35 meters (m) in height, and often including a canopy, subcanopy, shrub, and an herbaceous layer (composed of nonwoody plants). The classification of Hawaiian mesic forest is based on elevation, moisture, and physiognomy (aspect or appearance). Physiognomic classes of mesic forest are based on percentage cover of the dominant plant life-form in the uppermost vegetation layer. A mesic forest is a forest type that is neither wet nor dry (Sailer, 2006). Those classified as "mesic forest" have a moderate amount of moisture and greater than 25% forest cover (Gagne and Cuddihy, 1999).

Geology

Mesic forest substrates are highly variable but are generally well-drained and include rocky, shallow, organic muck soils, steep rocky talus (accumulation of rock debris) soils, shallow soils over weathered rock in steep gulches, and deep soils over soft weathered rock and gravelly alluvium (soils composed of clay, silt, sand, and gravel) (Gagne and Cuddihy, 1999).

Vegetation Structure and Composition

Vegetation structure and composition is variable throughout the mesic forests. Structure ranges from open to dense and mostly evergreen tree layer ranging from 2 to 35 m tall (Gagne and Cuddihy, 1999).

Other Biotic Components

Many of the relationships between trees and their environment are reciprocal: rain, temperature, humidity, and soil fertility influence tree growth, while trees affect microclimate, and soil moisture, structure, acidity, and fertility. Among the most important and well-studied tree-soil relationships are nutrient cycles, whereby plants take up the mineral elements essential for growth from the soil solution and return those elements to the soil via litterfall and root decay. Nitrogen (N-fixing) is particularly important in providing nutrients essential for growth and regeneration for plants and trees (Rowe et al., 2017). As a dominant and N-fixing canopy tree species in many Hawaiian mesic forests, native *Acacia koa* (koa) adds substantial benefits to soils by increasing nitrogen (Baker et al., 2009).

Biodiversity

The biodiversity in mesic forests is high compared to other ecosystems in the Hawaiian Islands (USFWS, 2016). Mesic forests contain areas with many microclimates that support a high species diversity. Diverse native mesic forests support many native bird and invertebrate species, and Hawai'i's only terrestrial mammal, the Hawaiian hoary bat, or 'ōpe'ape'a (*Lasiurus cinereus semotus*) (TNCH, 2006; Sailer, 2006).

Physical/Life History Components

Water availability

Rainfall influences the availability of water for plants and is a critical component of mesic forests. Tree species and vegetation typically found in mesic forests require moist conditions throughout the year. If water availability changes substantially, the biome may no longer be favorable for mesic forest vegetation that prefer a moist environment, and the altered biome may shift to a drier or wetter biome classification if the species shift is substantial. The density and diversity of tree species found in lowland mesic forests tends to increase with elevation and rainfall and decreases in lower elevations that receive less rainfall (Gagne and Cuddihy, 1999). The montane-subalpine mesic forests are found in regions that lack sufficient rainfall to support a wet forest, but that do not suffer moisture deficits for prolonged periods (Gagne and Cuddihy, 1999). Water can be a major limiting factor for the growth of some dominant native tree species in mesic forests, particularly koa, especially toward the drier end of its climatic range (Baker et al., 2009).

Viability of mesic forests

The viability of Hawaiian mesic forests depends on maintaining multiple and distributed populations (redundancy) of sufficient quality and size (resiliency) with species richness and genetic range (representation) to survive across the biome over time.

We define redundancy by the number, distribution, and connectivity of subunits that make up a biome. By resiliency we refer to the overall health, stability, quality and quantity of subunits that compose a biome. We define Representation, by the range of variation that exists within subunits that make up a biome, including environmental conditions and features (geographic, ecological, and climatic).

Adequate distribution across the landscape of mesic forests contributes to its ability to perpetuate after a catastrophic event in one area by having a redundant population in another area. Natural recruitment in the mesic forest is driven by dispersal, rainfall, light, and nutrient availability. Forest birds provide a vital role in seed dispersal in mesic forests to maintain and establish new forested areas (Culliney, 2011). Native invertebrates also serve an important role in the pollination of plant species found in mesic forests (Magnacca, 2007). Seabirds contribute an important source of marine derived nitrogen to the mesic forests through deposition of guano at their nesting sites (Rowe et al., 2017).

Conditions needed by mesic forests to develop are influenced by numerous factors including disturbance (fires, volcanism, storms, pathogens, and insect pests) as well as by rainfall, light, and nutrient availability. Shade limits the recruitment of some dominant mesic forest tree species, particularly koa, which grow best in forest clearings (Baker et al., 2009).

The quality and quantity of mesic forest contributes to its resiliency in the face of stochastic events. Most native species in this biome are not specifically fire-adapted, however, many species regenerate after disturbance if environmental conditions are optimal. Fire can reset the successional clock of this system by removing a substantial amount of plants. Some seeds will survive and be able to germinate following the fire, however, others rely on dispersal from other sources such as the wind or animals.

Diversity within and among locations of mesic forest is necessary to enhance its ability to adapt to change. Mesic forests are best represented when there is geographic and genetic diversity across the range. Representation considerations for mesic forests include presence on each of the main Hawaiian Islands spanning across both leeward and windward slopes, and from lowland to montane elevations.

The mesic forest ecosystem occurs throughout the State on most of the main Hawaiian Islands including Hawai'i, Moloka'i, Maui, Kaua'i, O'ahu, and Lāna'i on slopes ranging from 30 to 2000 m in elevation. Annual rainfall ranges from 1200 to 2500 millimeters (mm) per year (Gagne and Cuddihy, 1999). Price et al. (2007) further classified the mesic zone into "Moist-mesic" and "Seasonal-mesic" categories based on precipitation and elevation. Mesic forest stands are found in the mesic seasonal zone between the dry leeward and wet windward climates. These sites are considered too dry to support rainforests but typically do not experience extended periods of drought like the dry forests (Cuddihy and Stone, 1990).

Mesic forest subtypes include two native and two introduced communities: lowland mesic montane-subalpine mesic, introduced wet-mesic, and introduced managed tree plantation.

Prehuman Condition

Historically the lowland and montane mesic forests were found on the islands of O'ahu, Maui, Kaua'i, and Hawai'i, and to a lesser extent, on Moloka'i and Lāna'i. Although mesic forests were found historically on all of the main Hawaiian Islands, the majority occurred on the islands of Hawai'i and Maui (Figs. 1–4).

Fig. 1 Historical and current extent of the mesic forest system on the island of Hawai'i. Reeves, M.K. and Amidon, F. (2018). *Habitat Status Assessment Methods—Hawaii, Current Condition Summaries*. Technical Report from United States Fish and Wildlife Service. Honolulu, HI: Pacific Islands Fish and Wildlife Office, pp. 439, August 2018.

The original vegetation cover prior to the arrival of the Polynesians to the main Hawaiian Islands may be inferred from existing vegetation, remnants in disturbed areas, patterns of climate and substrates, and a few fossilized remains. Forests were and are the natural vegetation of most of the main Hawaiian Islands. On the six main Hawaiian islands with elevations exceeding 1000 m, the climate promotes forest development except in the alpine zones and in the driest parts of the leeward lowlands (Cuddihy and Stone, 1990). The mesic forest zone occupied both windward and leeward slopes. It occurred in regions transitional between wet and dry areas, in rain shadows, or at elevations above a temperature inversion layer on the higher islands, usually between 1525 and 2135 m elevation (Cuddihy and Stone, 1990).

Fig. 2 Historical and current extent of the mesic forest system on the islands of Moloka'i, Lāna'i, Maui and Kaho'olawe.

Fig. 3 Historical and current extent of the mesic forest system on the islands of Kaua'i and Ni'ihau.

Fig. 4 Historical and current extent of the mesic forest system on the island of O'ahu.

Mesic forests were more extensive historically, particularly in the lowlands, and contained inclusions of native grasslands and shrublands throughout the areas they occurred. Prior to human contact this biome encompassed an area up to 297,074 ha (734,086 ac) as indicated (cross-hatched) in Figs. 1–4.

Prehuman Mesic Forest Subtypes

Before the arrival of humans, mesic forest included two subtypes: lowland mesic forests and montane-subalpine mesic forests. Vegetation commonly found in these subtypes are included in Table 1.

Table 1 Diagnostic species found in prehuman mesic forest subtypes in Hawai'i.

Lowland mesic forest	Montane-subalpine mesic forest
<i>Acacia koa</i>	<i>Acacia koa</i>
<i>Alectryon macrococcus</i>	<i>Coprosma</i> spp.
<i>Antidesma pulvinatum</i>	<i>Dryopteris</i> spp.
<i>Charpentiera</i> spp.	<i>Leptecophylla tameiameia</i>
<i>Chrysodracon</i> spp.	<i>Metrosideros polymorpha</i>
<i>Cryptocarya mannii</i>	<i>Myoporum sandwicense</i>
<i>Ctenitis squamigera</i>	<i>Myrsine</i> spp.
<i>Diospyros sandwicensis</i>	<i>Nestegis sandwicensis</i>
<i>Doodia</i> spp.	<i>Pelea</i> spp.
<i>Flueggea neowawraea</i>	<i>Pipturus albidus</i>
<i>Metrosideros polymorpha</i>	<i>Pleomele</i> spp.
<i>Nestegis sandwicensis</i>	<i>Rubus hawaiiensis</i>
<i>Pisonia</i> spp.	<i>Sadleria</i> spp.
<i>Pritchardia kaalae</i>	<i>Sapindus</i> spp.
<i>Rhus sandwicensis</i>	<i>Santalum</i> spp.
<i>Strongylodon ruber</i>	<i>Uncinia uncinata</i>

Hawai'i lowland mesic forest: This mesic forest subtype occurred on the islands of Hawai'i, Moloka'i, Maui, Kaua'i, and O'ahu. Stands occurred in the mesic zone between the dry leeward and wet windward climates. Vegetation composition was variable, ranging from an open to dense tree layer. There was often a diverse canopy, subcanopy, and tall-shrub layers with lianas (Gagne and Cuddihy, 1999). These forests would usually grade into lowland wet forests upslope. At their lower limits they would grade into either lowland mesic shrublands, lowland dry shrublands, or lowland dry forests, depending on topography, and moisture (Gagne and Cuddihy, 1999). Seven subcategories of native lowland mesic forests are recognized: 'Ōhi'a lowland mesic forest, Koa lowland mesic forest, Olopuia lowland mesic forest, Lama/'Ōhi'a lowland mesic forest, Diverse lowland mesic forest, Loulu lowland mesic forest, and Pāpala kēpau/Pāpala lowland mesic forest (Gagne and Cuddihy, 1999; Table 2).

Hawai'i montane-subalpine mesic forest: This subset of the mesic forest system occurred on the montane and subalpine slopes of Kaua'i, Maui, and Hawai'i. Montane mesic forests occurred above the 'Ōhi'a lowland wet forest, below montane wet forests, and leeward of koa/'Ōhi'a montane wet forests (Gagne and Cuddihy, 1999). The understory was variable and composed of sedges, ferns, and shrubs (Gagne and Cuddihy, 1999). Four subcategories are recognized under the mesic montane-subalpine subtype: 'Ōhi'a montane mesic forest, Koa/'Ōhi'a montane mesic forest, Koa/'Ōhi'a/A'e mesic forest, and Olopuia montane mesic forest (Gagne and Cuddihy, 1999; Table 2).

Redundancy, Representation, and Resiliency

Redundancy

Both lowland mesic and montane-subalpine mesic forests were widely distributed historically across a broad range in the main Hawaiian Islands (Figs. 1–4). This redundancy made mesic forests less susceptible to catastrophic events such as an occasional hurricane or volcanic eruption. In the case of lava flows, these were localized events affecting only some populations of mesic forests across the biome. The distribution of mesic forest in multiple units across the landscape and across the islands provided redundancy, which provided the ability to withstand events only affecting smaller areas of mesic forests on individual or a few islands (e.g., single volcanic eruptions or hurricanes affecting multiple islands).

Representation

Historically, mesic forests were found throughout the main Hawaiian islands (Hawai'i, Moloka'i, Maui, Lāna'i, Kaua'i, and O'ahu) and across multiple watersheds (representation). They occurred on both windward and leeward slopes as well as across a broad range of substrates from the oldest on Kaua'i to the youngest on Hawai'i. Since mesic forests were found across a diversity of subunits historically it is likely that natural stochastic events (fires, hurricanes, etc.) did not severely impact the biome. Greater representation of mesic forest subunits would have provided more opportunity for the biome to adapt and evolve under changing conditions.

The diversity of tree species found within mesic forests historically also contributed to high representation (the ability to adapt to changing environmental conditions and is measured by the variation across the landscape) found in this ecotype. Prior to human arrival, all plants, animals, and invertebrates arrived in Hawai'i by accident or by drift. Because of this isolation, species were able to fill empty niches not already occupied by other species that lead to speciation (adaptive radiation) and a high rate of endemism. This endemism and diversity existed across the pre-human mesic forest subtypes, thus leading to high representation.

Resiliency

Lowland mesic and montane-subalpine mesic forests were historically found in multiple areas containing high quality subunits with a wide range of species and diversity. Healthy and stable high quality mesic forest areas would have enabled the biome to withstand natural, annual variations in the environment and recover from periodic disturbances (i.e., floods, minor fires, etc.). Should a natural disturbance have occurred, the amount and quality of mesic forest, and the range and diversity of species composing the seed bank, would have allowed the mesic forest to recover, making it resilient.

Intact, high quality, native mesic forests are resilient and are able to recover after natural stochastic events. Koa and 'Ōhi'a, both dominant mesic forest tree species, have been observed to regenerate following stochastic disturbances such as lava flows, fires, and hurricanes. The principal natural ignition sources of fires in Hawai'i before human settlement were lava flows and lightning but these events were infrequent and did not have major impacts on mesic forests (TMA, 2007; Abrahamson, 2013).

A number of native plant species are fire-tolerant, although no native plant is fire-resistant (Smith and Tunison, 1992). Koa, like other *Acacia* species, has many traits of a fire-adapted species, such as seeds that persist for years or decades in the soil and require scarification for germination. Although koa trees may be killed by high-intensity fires, disturbance by fire has been shown to stimulate their germination (Scowcroft and Wood, 1976; Baker et al., 2009). Other species found in mesic forests that are fire-tolerant, include naio (*Myoporum sandwicense*), 'ō'hia, tree ferns (*Sadleria cyatheoides*), and the native grasses, *Deschampsia nubigena*, and *Eragrostis* spp. (Mueller-Dombois, 1981; Mueller-Dombois and Fosberg, 1998; Smith and Tunison, 1992; Baker et al., 2009).

It is reasonable that mesic forests prior to human contact showed similar or higher resiliency. Mesic forest regeneration likely occurred through transportation of seeds by wind and native birds (Carlquist, 1980). Native forest birds and insects were also important pollinators (Cox and Elmqvist, 2000) while seabirds contributed an important source of nitrogen through deposition of guano (Rowe et al., 2017).

Table 2 Characteristics of current mesic forest subtypes in Hawai'i (Gagne and Cuddihy, 1999; Landfire, 2016).

Mesic forest subtypes (and subcategories)	Precipitation (mm)	Elevation (m)	Characteristic plants
Lowland mesic forest <i>Subcategories of lowland mesic forests</i> <i>Native:</i> • 'Ōhi'a • Koa • Olopuā • Lama/'Ōhi'a • Diverse • Loulu • Pāpala kēpau/Pāpala <i>Nonnative:</i> • Kukui • Christmas berry • Guava • Ironwood Silk oak	Between 1200 and 3800 mm	Between 30 and 1600 m	Native species: <i>Metrosideros polymorpha</i> ('ōhi'a), <i>Acacia koa</i> (koa), <i>Diospyros sandwicensis</i> (lama), <i>Nestegis sandwicensis</i> (olopua), <i>Chrysodracon</i> spp. (halapepe), and <i>Pritchardia kalae</i> (loulu), <i>Antidesma pulvinatum</i> (hame), <i>Cryptocarya mannii</i> , <i>Alectryon macrococcus</i> (māhoe), <i>Charpentiera</i> spp. (pāpala), <i>Flueggea neowawraea</i> (mēhamehame), <i>Rhus sandwicensis</i> (neneleau), <i>Pisonia</i> spp., <i>Canthium odoratum</i> (alaha'e), <i>Ctenitis squamigera</i> (pauoa fern), <i>Doodia</i> spp. ('ōkupukupu fern), <i>Strongylodon ruber</i> (nuku'i'iwi), and <i>Freyinetia arborea</i> ('ie'ie). Nonnative species: <i>Schinus terebinthifolius</i> (Christmas berry), <i>Aleurites moluccana</i> (kukui), <i>Psidium guajava</i> (common guava), <i>Psidium cattleianum</i> (strawberry guava), <i>Syzygium</i> spp. (roseapple), <i>Casuarina equisetifolia</i> (ironwood), <i>Grevillea robusta</i> (silk oak), <i>Alocasia macrorrhiza</i> (giant taro), <i>Nephrolepis</i> spp. (sword fern), <i>Passiflora suberosa</i> (passionfruit), <i>Cordyline fruticosa</i> (Ti), <i>Rubus rosifolius</i> (thimbleberry), and <i>Clidemia hirta</i> (Koster's curse)
Montane-subalpine mesic forest <i>Subcategories of montane-subalpine mesic forests</i> <i>Native:</i> • 'Ōhi'a • Koa/'Ōhi'a • Koa/'Ōhi'a/A'e • Olopuā	Between 1000 and 3800 mm	Between 900 and 2000 m	<i>Metrosideros polymorpha</i> ('ōhi'a), <i>Acacia koa</i> (koa), <i>Sapindus saponaria</i> (a'e), <i>Nestegis sandwicensis</i> (olopua), <i>Coprosma</i> spp. (pilo), <i>Myrsine</i> spp. (kōlea), <i>Pisonia</i> spp., <i>Myoporum sandwicense</i> (naio), <i>Sophora chrysophylla</i> (māmane), <i>Leptecophylla tameiameia</i> (pūkiawe), <i>Pipturus albidus</i> (māmaki), <i>Rubus hawaiiensis</i> ('ākala), <i>Strongylodon ruber</i> (nuku'i'iwi), and ferns such as <i>Dryopteris</i> spp., and <i>Sadleria</i> spp. Nonnative species: <i>Cenchrus clandestinus</i> (Kikuyu grass), <i>Ehrharta stipoides</i> (meadow rice grass), and <i>Tropaeolum majus</i> (garden nasturtium)
Introduced wet-mesic forest	Generally between 1200 and 1900 mm	Generally below 1000 m, but occasionally higher elevations	<i>Bambusa</i> spp. (bamboo), <i>Casuarina</i> spp. (ironwood), <i>Psidium</i> spp. (guava), <i>Grevillea</i> spp. (silk oak), <i>Melaleuca leucadendra</i> (paper bark tree), <i>Melastoma candidum</i> , <i>Melochia umbellata</i> , <i>Miconia calvescens</i> , <i>Moluccan albizia</i> , and <i>Morella faya</i> (firetree)
Managed tree plantation	Generally between 1000 and 1900 mm	Generally between 30 and 1600 m	<i>Araucaria columnaris</i> (Cook pine), <i>Araucaria heterophylla</i> (Norfolk pine), <i>Eucalyptus</i> spp. (gum tree), <i>Pinus</i> spp. (pine), <i>Sequoia sempervirens</i> (redwood); horticulture; or agriculture (coffee, fruit, nut orchards). <i>Casuarina</i> spp. (ironwood), <i>Paraserianthes</i> spp. (albizia), <i>Fraxinus</i> spp. (tropical ash), <i>Melaleuca</i> spp., <i>Psidium</i> spp. (guava), <i>Grevillea</i> spp. (silk oak), and <i>Acacia koa</i> (koa)

Current Condition

Mesic forests are still found across multiple watersheds on all of the main Hawaiian Islands (Figs. 5–8). It is estimated that only 40% of the original mesic forest biome in the Hawaiian Islands currently remains (State of Hawai'i DLNR, 2016). Between ~400 and 1800 CE, Hawaiians settled, colonized, and reshaped much of the vegetation of the lowlands, including mesic communities, on all the major Hawaiian Islands (Kirch, 1982). In these ecosystems, Hawaiians used fire to clear land for agriculture (i.e., slash and burn). By the time of European contact in the late 1700s, most of the native mesic communities below 760 m were converted from forest and open woodlands to open grasslands (Cuddihy and Stone, 1990; Kirch, 1982). Much of the lowland mesic forest have since been converted to pasture, military or agricultural use, or have been lost to urbanization or fire (Cuddihy and Stone, 1990; State of Hawai'i DLNR, 2016). Intensive human disturbance in the lowlands has resulted in the majority of intact native mesic forests remaining only at higher elevations (The Nature Conservancy (TNC), 2006).

Mesic forests now include mixed native-introduced forests, highly disturbed mesic forests, and introduced plantations (Table 2). Many areas in the lowland and montane mesic forest zone have been cleared for timber logging, and have been invaded by invasive grasses brought in by early ranchers to support grazing animals (Juvik et al., 2008). Ranching activities and the subsequent increase and spread of invasive grasses has been the most important disruption of the montane mesic forests. Large expanses of koa/'ōhi'a montane mesic forest have been converted to cattle ranches after logging of koa. Browsing by feral pigs, goats and sheep, fires, and

Fig. 5 Current distribution of the mesic forest system on the island of Hawai'i.

clearing of land for commercial tree planting and harvest have also reduced the quality and extent of the mesic forests (Gagne and Cuddihy, 1999).

Because mesic forests are restricted in range and have been highly modified by human activity and introduced species, the ability of this ecotype to recover from stochastic events in unmanaged forest areas is greatly reduced, particularly in areas that have been

Fig. 6 Current distribution of the mesic forest system on the islands of Moloka'i, Lāna'i, Maui, and Kaho'olawe.

Fig. 8 Current distribution of the mesic forest system on the island of O'ahu.

fragmented by timber extraction and conversion of forests to cattle pasture. Wildfires are also a serious threat to both lowland and montane mesic forests.

Mesic forests currently include two native dominated subtypes: lowland mesic forest and montane-subalpine mesic forest, and two introduced subtypes: introduced wet-mesic forest, and introduced mesic managed plantations. Characteristics of the forest subtypes are described in [Table 2](#).

Current Mesic Forest Subtypes

Hawai'i lowland mesic forest: This subset of the mesic forest system still occurs on the mesic slopes of Hawai'i, Moloka'i, Maui, Kaua'i, and O'ahu. Lowland areas have been heavily impacted by disturbance and displacement, leaving remnant native areas at higher elevations ([The Nature Conservancy, 2006](#)). Seven native and five introduced lowland mesic forest communities are identified and are defined by dominant and codominant species ([Table 2](#)). The native communities include: 'Ōhi'a (*Metrosideros polymorpha*) lowland mesic forest, Koa (*Acacia koa*) lowland mesic forest, Olopua (*Nestegis sandwicensis*) lowland mesic forest, Lama/'Ōhi'a (*Diospyros/Metrosideros*) lowland mesic forest, Diverse lowland mesic forest, Loulu (*Pritchardia*) lowland mesic forest, and Pāpala kēpau/Pāpala (*Pisonia/Charpentiera*) lowland mesic forest ([Gagne and Cuddihy, 1999](#)). Introduced lowland mesic forest communities include: Kukui (*Aleurites*), Christmas berry (*Schinus*), Guava (*Psidium*), Ironwood (*Casuarina*), and Silk oak (*Grevillea*) lowland mesic forests ([Gagne and Cuddihy, 1999](#)). The diversity of native species that remain in the introduced forests is likely related to the level of human disturbance ([Gagne and Cuddihy, 1999](#)). Most of the remaining native mesic lowland forests are dominated by lama (*Diospyros sandwicensis*) or 'ōhi'a (*Metrosideros polymorpha*) where they may occur in mixed stands. They are generally found in areas with rocky or steep slopes, or in gulches where human development is limited by terrain.

Hawai'i montane-subalpine mesic forest: This mesic montane-subalpine forest system still occurs on Kaua'i, Maui and Hawai'i. The island of Hawai'i contains the majority of this subtype while the islands of Maui and Kaua'i contain only a few thousand acres each ([Cuddihy and Stone, 1990](#)).

Four native communities are recognized as subcategories under the mesic montane-subalpine subtype: 'Ōhi'a montane mesic forest, Koa/'Ōhi'a montane mesic forest, Koa/'Ōhi'a/ A'e forest, and Olopua montane forest ([Gagne and Cuddihy, 1999](#)). Characteristics of these forests are described in [Table 2](#).

Hawai'i introduced wet-mesic forest: This introduced vegetation cover type is common on lower elevation wet-mesic sites. It has developed in areas that would have been dominated historically by native vegetation found in lowland mesic forests. Introduced

forests are a result of human activity including land conversion due to agricultural practices, development, and due to the introduction and establishment of nonnative species. The tree canopy is typically dominated by a variety of introduced wet or mesic tree species (Gagne and Cuddihy, 1999; Landfire, 2016) (Table 2).

Hawai'i managed tree plantation: The Hawai'i managed tree plantation typically consists of stands of introduced trees planted for forest products (lumber and fuel); horticulture; or agriculture (coffee, fruit, nut orchards) (Landfire, 2016; Table 2). Many of the plantations were also planted on converted agricultural land (sugarcane) to provide soil and water conservation benefits (State of Hawai'i DLNR, 2017). Plantations typically occur at lowland and montane, wet-mesic to mesic settings, often at the lower elevation edge of forest reserves (Landfire, 2016).

With awareness in the late 19th and early 20th century of the damage caused to native forests from grazing, logging, and feral animals, and the importance of forest cover to provide water for the sugar industry, large private forest reserves (planted mostly in nonnative species) were established at Līhu'e, Kaua'i 4050 ha (10,008 ac), and Pāhala, Hawai'i 20,240 ha (50,014 ac), and plantings for watershed protection on Maui and O'ahu (Cuddihy and Stone, 1990). At the beginning of the 20th century, in the early days of the territorial forest reserve, tree plantings for forest restoration were primarily of introduced fast growing tropical species. Native species and commercially valuable timber trees were avoided so that future generations would not be tempted to harvest trees (Cuddihy and Stone, 1990). Today managed tree plantations are commercially valuable trees harvested for lumber and fuel and total 12,379 ha (30,589 ac) statewide (Reeves and Amidon, 2018). The vast majority of plantations found within mesic forests are categorized as mixed (7321 ha; 18,090 ac) and contain stands of both native and introduced tree species. Mesic plantations categorized as "disturbed" total approximately 4449 ha (10,994 ac), and those containing less than 5% vegetation total ~2.4 ha (6 ac) statewide. Native tree plantations (primarily koa) are still at an experimental stage in Hawai'i. In spite of being a high-quality wood with high demand in local and foreign markets, native koa plantations have not gone through a full rotation (State of Hawai'i DLNR, 2017; Inman-Narahari, 2015). Native-dominated koa plantations total ~607 ha (1500 ac) statewide and compose a small proportion (<1%) of the available mesic forest plantations (Reeves and Amidon, 2018).

Interest in koa silviculture has grown in recent decades on deforested lands to supply demand for this valuable hardwood. These native dominated plantations often support an under story of native species (Skolmen and Fujii, 1980; Baker et al., 2009). Koa silviculture practiced on old pasturelands has resulted in increased habitat for some native species including endangered and common Hawaiian forest birds (Pratt and Jacobi, 2009).

Extent/Quantity of Mesic Forests

The extent of Hawai'i mesic forest today is similar across all islands to the prehuman condition, except for substantial loss of lowland mesic forests on the islands of O'ahu, Kaua'i, and Lāna'i (Figs. 6–8), and intrusion of lowland mesic forests by invasive trees, shrubs, and nonnative grassland communities. In total, there are approximately 175,175 ha (432,867 ac) of mesic forest currently found in the main Hawaiian Islands (Table 3). Although mesic forest is found on all of the main Hawaiian Islands, over half occur on the island of Hawai'i (Table 3). Thirty-eight percent (66,335 ha; 163,917 ac) of Hawai'i's mesic forest is native species dominated (i.e., greater than 50% native) (Fig. 10). The remaining portion (52%) is composed of nonnative species mixed forests (90,963 ha; 224,774 ac), or in a system described as heavily disturbed or bare, (containing <5% vegetation cover) (17,874 ha; 44,168 ac) which accounts for ~10% of the current vegetation quality found in Hawai'i mesic forests (Reeves and Amidon, 2018). Managed tree plantations compose 12,380 ha (30,592 ac) of mesic forests in Hawai'i. This constitutes ~7% of all mesic forests. The large majority of mesic forest plantations occur on the island of Hawai'i (8538 ha; 21,098 ac) with smaller plantations on O'ahu (2340 ha; 5782 ac), Moloka'i (811 ha; 2004 ac), and on Kaua'i (691 ha; 1707 ac) (Fig. 9).

Native dominated mesic forests are still found on the islands of Hawai'i (46,590 ha; 115,126 ac), Kaua'i (6001 ha; 14,829 ac), Maui (4317 ha; 10,667 ac), Moloka'i (4670 ha; 11,540 ac), O'ahu (4677 ha; 11,557 ac), and Lāna'i (79 ha; 195 ac). The greatest percentage of native dominated mesic forests occur on the islands of Hawai'i and Moloka'i (>50% remain on both islands) (Fig. 10).

There are eight vegetation classifications for Hawai'i mesic forest based on canopy height and dominant tree species (Reeves and Amidon, 2018). These are closed koa-ōhi'a mesic forest, closed 'ōhi'a mesic forest, mixed native non-native mesic forest, native

Table 3 Current distribution of mesic forest in the main Hawaiian Islands (Reeves and Amidon, 2018).

Island	Area in acres (hectares)	Area (% of Island)	Area (% of state of Hawai'i)
Lāna'i	952 (385)	1	< 1

mesic to dry forest and shrubland, nonnative mesic forest, open koa-‘ōhi’a mesic forest, open ‘ōhi’a mesic forest, and plantation forest (Fig. 9).

Land Ownership

Over 46% (80,715 ha; 199,451 ac) of mesic forest in the Hawaiian Islands is owned by the federal, state, and local government. The remaining mesic forests exist on private land (Fig. 11; Table 4; Reeves and Amidon, 2018).

Stressors

Hawaiian mesic forest ecosystems are highly vulnerable to impacts of stressors due to climate change as well as nonclimate stressors since they are sensitive to biotic and abiotic factors associated with both (Hilberg et al., 2018). Table 5 lists the climate and non-climate stressors for mesic forests which are described in further detail below.

Fig. 10 Quality of mesic forest system.

Climate Stressors

Precipitation, wind, drought, soil moisture, air temperature, and storms

Mesic forests are susceptible to hurricanes, high winds, and landslides that may affect vegetation, alter succession, and create conditions more favorable to invasive species growth resulting in an altered vegetation community (Hilberg et al., 2018). Tree species found in mesic forests are somewhat wind-resistant but koa, which have shallow root systems, are vulnerable to snapping and uprooting in extremely high winds associated with storms (Baker et al., 2009). Storm related flooding and landslides can destroy mesic forests and alter succession, particularly in areas with poor drainage or on steep ridges and valleys (Restrepo and Vitousek, 2001; Walker, 1999). One of the most sensitive climatic components for mesic forests is water availability as a function of precipitation, soil moisture, drought, air temperature, and presence of trade winds. For example, reduced or increased water availability can directly alter vegetation composition and distribution in these communities by favoring growth and germination of invasive plants with higher tolerance for drier or wetter conditions (Hilberg et al., 2018).

A primary question regarding the possible impacts of rising temperatures on local climate in Hawai'i is whether the trade wind inversion layer will be affected. If the height or frequency of the inversion changes due to warming, significant hydrological, and ecological changes can be expected (Loope and Giambelluca, 1998; Krushelnycky et al., 2016). The impact of climate on mesic forests varies across the main Hawaiian Islands. On Maui and Hawai'i where higher elevation environments exist, continued warming may result in an upslope shift of mesic forests (Vorsino et al., 2014).

Fig. 11 Summary of mesic forest land ownership.

Nonclimate Stressors

Invasive species

Invasive species are nonnative organisms whose introduction causes or is likely to cause economic or environmental harm or harm to human health. They are a prominent stressor for the Hawaiian mesic forest ecosystem as many of the native species evolved in isolation on the islands in the absence of mammalian herbivores and plant competitors (Weller et al., 2011; Dunkell et al., 2011). Some invasive plants are less susceptible to drought and less palatable to invasive herbivores and therefore may thrive when disturbance events occur and outcompete the native mesic forest vegetation (Weller et al., 2011). Nonnative grass competition reduces recruitment of native tree and shrub species in mesic forests and also reduces the availability of water and nutrients to native trees and shrubs (Denslow et al., 2006). Depredation of seeds and seedlings by invasive rodents including rats (*Rattus rattus*, *R. norvegicus*, and *R. exulans*), and mice (*Mus musculus*) can also inhibit growth and regeneration of native species (Shiels, 2010). Feral ungulates (pigs, goats, cattle, and deer) consume and trample new growth and seedlings of native vegetation, and also promote the spread of invasive plant seeds through fecal matter causing further degradation of mesic forests (Dunkell et al., 2011).

Primary threats to lowland mesic forests are caused by feral animals (pigs, goats, deer, and cattle), fires, and subsequent invasion of weeds and grasses including *Andropogon virginicus*, *Panicum maximum*, *Cenchrus clandestinus*, *Schizachyrium condensatum*, *Clidemia hirta*, *Melastoma candidum*, *Psidium cattleianum*, and *Psidium guajava* (Gagne and Cuddihy, 1999).

Agriculture, grazing, and urban development

Since the 19th century Hawaiian forests have undergone severe stress from grazing by cattle and livestock and other agriculture uses on the landscape. Many of the mid-elevation mesic forests have been transformed into grassland pastures composed of invasive

Table 4 Land ownership of mesic forest in Hawai'i (Reeves and Amidon, 2018).

	Biological

species after timber has been harvested. Mesic pasture conversion has occurred across 69,483 ha (171,696 ac) in the main Hawaiian Islands. The largest proportion of mesic forest pasture conversion is seen on the island of Hawai'i (23,916 ha; 59,098 ac) and Maui (3296 ha) (NOAA, 2018).

It was recognized as early as the mid-1800s that cattle grazing impacted many types of native vegetation and especially egeneration of koa (Cuddihy and Stone, 1990). The consumption of seedlings and saplings by cattle directly prevents the successful regeneration of mesic forests (Blackmore and Vitousek, 2000; Mueller-Dombois, 1992) and competition with nonnative pasture grasses impedes the germination of native seeds (Baker et al., 2009). Continued grazing, soil compaction, and loss of the canopy trees has resulted in persistence of the grasslands rather than regeneration of the native mesic forests (Denslow et al., 2006).

Continued human population growth on all of the main Hawaiian Islands has increased the need for additional housing and development (State of Hawai'i, 2016). Additional development threatens destruction of the mesic forest biome where it occurs on private land (Fig. 11).

Much of the lowland mesic forest has been converted to pasture or agricultural use (crops and timber production), or has been lost to urbanization or fire (Cuddihy and Stone, 1990; SABP, 2015). Military training activities have also impacted mesic forest areas through live-fire training, large-scale troop movements, and heavy equipment operations. These activities impact mesic areas at United States Army training facilities on O'ahu. Training operations have resulted in vegetation clearing, increases in wildfire frequency, and the introduction and spread of unwanted alien species (State of Hawai'i DLNR, 2016).

Insects and disease

The nonnative acacia psyllid (*Psylla uncatoides*) breeds and feeds on the new terminal growth of koa and infestations by this insect can cause terminal growth dieback in mesic koa stands (Baker et al., 2009).

In early 2005, a fungal disease was found in 'ōhi'a trees on O'ahu. The disease, named 'ōhi'a rust (*Puccinia psidii*), has since spread to all the main Hawaiian Islands, where it affects other Myrtaceae taxa. In severe infections, terminal growth will die back (TMA, 2007).

Another significant threat, koa wilt disease, caused by *Fusarium oxysporum*, threatens the health of koa (*Acacia koa*), one of the two dominant tree species in Hawai'i's native forests. This soil-borne disease causes dieback and decline of koa in native forests by compromising the tree's vascular system (State of Hawai'i DLNR, 2016). Young trees less than 15 years old seem to be affected more often than old trees, and the disease is more often seen on trees planted below 760 m elevation than on trees growing in the forest at higher elevations. Koa wilt has been observed on the islands of Hawai'i, Maui, O'ahu, and Kaua'i (TMA, 2007; Baker et al., 2009).

Rapid 'Ōhi'a death is a disease that was first identified on the island of Hawai'i in 2010. The disease is caused by two fungal pathogens, *Ceratocystis lukuohia* and *Ceratocystis huliohia*. Both fungal pathogens kill 'ōhi'a which is a significant component of mesic forests (Barnes et al., 2018). Since 2010 the disease has spread to over 30,300 ha (75,000 ac) on the island of Hawai'i with some stands showing a greater than 90% mortality within 2–3 years. In 2018 the disease was also detected on the island of Kaua'i. The primary path for *Ceratocystis* to enter 'ōhi'a plants is through a wound which can occur following an injury due to cutting, pruning, sawing, breakage, strong winds, root abrasion, ungulate damage, and root trampling (CTAHR, 2018).

Wildfire

The proliferation of invasive grasses adapted to fire and the increased incidence of human ignited fires have resulted in an altered fire regime that is more frequent and severe, and increasing as much as fivefold in frequency since the 1970s (Abrahamson, 2013).

Throughout much of the state, particularly in lowland mesic areas, highly flammable nonnative grasses have replaced less flammable native communities (Abrahamson, 2013). The fire potential is greatest in areas subjected to seasonal drought, particularly in native ecosystems below 1400 m, in areas invaded by alien grasses and previously affected by fire (Smith and Tunison, 1992).

The montane parkland mesic ecosystem has shown some adaptation to fire (Mueller-Dombois, 1981), with rapid recovery of some native mesic forest species, particularly koa. Fire potential is relatively high in the montane mesic zone because of the continuous arrangement of grasses and abundance of shrubs. The invasion of alien grasses is increasing the fire potential in this ecological zone (Smith and Tunison, 1992; USFWS, 2010).

Postfire regeneration of native species is also impaired by invasive grasses which compete with native seedlings for water, light, and nutrients, and serve as fuel for future fires (Baker et al., 2009).

Natural disasters

Mesic forests are susceptible to natural disasters such as volcanic eruptions that remove vegetation and alter succession (Hilberg et al., 2018). These events can cause extensive damage over short time periods but are localized in their extent and occur only on the volcanically active island of Hawai'i. Regeneration of native mesic forest plants and trees is slow, beginning with the growth of lichens and pioneer species. Substrate age, climatic moisture, and elevation are the primary drivers of rates of succession. Succession in the mesic zone is slower than in wet areas but faster than in dry and arid regions (Carlquist, 1980; Price et al., 2007).

Biological

The recent and continued significant population decline of seabirds has a negative impact on mesic forests. Seabirds contribute marine derived nutrients, especially nitrogen, to the mesic forest ecosystems through deposition of guano (Rowe et al., 2017). In addition, the loss of native forest birds and pollinators has reduced the pollination of native plant and tree species resulting in lower rates of regeneration of native species (Aslan et al., 2013; Price and Wagner, 2004).

Conservation Efforts

Reserves

Approximately 25,683 ha (63,464 ac) of mesic forests are protected in reserve areas across the main Hawaiian Islands (Fig. 12). Reserve areas may include areas designated as a national park, national wildlife refuge, Natural Area Reserve (NAR), private reserve, or Nature Conservancy preserve (Reeves and Amidon, 2018). The amount of mesic forest protected in reserve areas varies by island, with 18,292 ha (45,200 ac) on the island of Hawai'i, 3615 ha (8933 ac) on Maui, 1867 ha (4613 ac) on Kaua'i, and 1384 ha (3420 ac) on Moloka'i (Fig. 12). Of 18,292 ha (45,200 ac) protected in reserves areas on the island of Hawai'i, roughly 15,304 ha (37,817 ac) (84%) are classified as native dominated habitat (Fig. 12). Lāna'i and O'ahu contain the least amount of mesic forest protected in reserve areas in the State with 49 ha (121 ac) on Lāna'i and 482 ha (1191 ac) on O'ahu (Fig. 12). Knowing that less than 25,683 ha (63,464 ac) of mesic forests are protected in reserve areas in the state, and 175,175 ha (432,867 ac) are actually classified as mesic forests in the state, indicates a need to implement additional measures to increase the public's awareness of the remaining gap between unprotected versus protected mesic forests. Conservation areas that contain mesic forests in the state are listed in Table 6. Management efforts within reserve areas may include wildfire threat control, invasive plant and animal control, and native forest restoration.

Fig. 12 Quality of mesic forests in reserves.

Table 6 Mesic forest conservation areas in Hawai'i.

<i>Island</i>	<i>Mesic forest subcategory</i>	<i>Name of reserve</i>	<i>Landowner</i>	<i>Number acres (hectares) protected</i>	<i>Year established</i>
O'ahu	Lowland mesic	Pahole Natural Area Reserve	State	658 (266)	1981
O'ahu	Lowland mesic	Mt. Ka'ala Natural Area Reserve	State	1100 (445)	1981
O'ahu	Lowland mesic	O'ahu Forest National Wildlife Refuge	Federal	4525 (1831)	2000
Kaua'i	Lowland and montane mesic	Ku'i'a State Natural Area Reserve	State	1636 (662 ha)	1981
Maui	Montane mesic	Nakula State Natural Area Reserve	State	4441 (1797)	2011
Maui	Montane mesic	Haleakalā National Park	Federal	33,265 (13,462)	1961
Hawai'i	Montane mesic	Hawai'i Volcanoes National Park	Federal	207,634 (84,027)	1916
Hawai'i	Montane mesic	Hakalau Forest National Wildlife Refuge	Federal	32,733 (13,247)	1985
Hawai'i	Montane mesic	Kona Refuge	Federal	5300 (2145)	2005
Hawai'i	Montane mesic	The Nature Conservancy—Kona Hema Preserve	Private	8089 (3274)	2003
Hawai'i	Montane mesic	Keauhou Forest—Kamehameha Schools, Three Mountain Alliance	Private	32,570 (13,181)	1985
Hawai'i	Montane mesic	Pu'uwa'awa'a State Forest Bird Sanctuary	State	3806 (1540)	2003
Hawai'i	Montane mesic	Manukā State Natural Area Reserve	State	25,714 (10,406)	1983

Laws and Biosecurity

Endangered species protections and biosecurity and invasive species laws, regulations, coordination, and authority aid in conservation efforts for mesic forests by preventing the introduction of invasive plants and providing legal protections for rare native species (Table 7).

Biosecurity

In addition to federal biosecurity laws (Executive Orders 11,987, 13,112, 13,751), the Hawai'i Invasive Species Council (HISC) adopted Resolution 17-1 endorsing the Hawai'i Interagency Biosecurity Plan. This Interagency Biosecurity Plan is the state's guiding document for biosecurity improvements over the coming decade.

Endangered species act (ESA)

The Endangered Species Act of 1973 (ESA) aims to provide a framework to conserve and protect endangered and threatened species and their habitats. As habitat loss is the primary threat to most imperiled species, the ESA allows the U.S. Fish and Wildlife Service (USFWS) and National Marine Fisheries Service (NMFS) to designate specific areas as critical habitat zones. In 1978, Congress amended the law to make critical habitat designation a mandatory requirement for all threatened and endangered species.

Nineteen percent (30,942 ha; 76,459 ac) of mesic forest habitat in the state of Hawai'i is designated as federal critical habitat for 305 threatened and endangered species in the main Hawaiian islands (Fig. 13). The majority of designated critical habitat that is also classified as mesic forest is located on the islands of Hawai'i (11,932 ha; 29,484 ac) and O'ahu (8291 ha; 20,487 ac) (Fig. 13). Species listed under the ESA are automatically added to the State of Hawai'i list of endangered species, and are thus also protected by State regulations.

Table 7 Laws and regulations

<i>Title</i>	<i>Year implemented</i>	<i>Authority</i>	<i>Intent/purpose</i>
Endangered Species Act	1973	Federal	Protects critically imperiled species from extinction
50 CFR 16	1974	Federal	Implements the Lacey Act (18 USC 42), which prohibits importation of injurious species
Convention on International Trade in Endangered Species	1975	International	Ensures that international trade in specimens of wild animals and plants does not threaten the survival of the species in the wild
Executive Order 11987	1977	Federal	Charges executive agencies with restricting the introduction of exotic species into the natural ecosystems on federal lands; and encourages States to do the same
Hawai'i Administrative Rules, Title 4, Subtitle 6, Chapters 68 and 70	1981	Hawai'i (Department of Agriculture, DOA)	Rules/amendments for noxious weeds, plant and nondomestic animal quarantine, plant import, and bromeliad import
Executive Order 13112	1999	Federal	Requires that a Council of Departments dealing with invasive species be created to prevent the introduction of invasive species and provide for their control and to minimize the economic, ecological, and human health impacts that invasive species cause
HRS 194-2	2002	Hawai'i (Department of Land and Natural Resources, DLNR)	Establishes Hawaii Invasive Species Council (HISC)
Act 85	2003	Hawai'i (HISC)	Conveys statutory authority to HISC to continue to coordinate approaches among the various State and Federal initiatives for the prevention and control of invasive species
Act 36 (2011) HRS 150A-5.3	2011	Hawai'i (DOA)	Imposes a fee for the inspection, quarantine, and eradication of invasive species contained in any freight brought into the State
HB 1568	2011	Hawai'i (DOA)	Requires commercial harbors and airports in Hawai'i to provide biosecurity and to facilitate cargo inspections
HRS 174C Hawaii State Water Code	2013	Hawai'i (CWRM)	Establishes Commission on Water Resource Management (CWRM) and Water Resource Management Fund
Executive Order 13751	2016	Federal	To prevent the introduction of invasive species and provide for their control, and to minimize the economic, plant, animal, ecological, and human health impacts that invasive species cause (amends EO 13112)
7 CFR 360.200	2018	Federal	Designates certain plants as noxious weeds

Fig. 13 Federally designated critical habitat on the main Hawaiian islands containing mesic forest.

Stakeholder Engagement

National parks and national wildlife refuges

A total of 16,671 ha (41,195 ac) of mesic forests exist on federal lands in the Hawaiian islands (Table 4). Of this, approximately 64% are found on the island of Hawai'i within Hawai'i Volcanoes National Park and in the Hakalau Forest and Kona National Wildlife Refuges (Table 6). Haleakalā National Park also contains native mesic forest resources on Maui (Tables 4 and 6). Management actions by these federal agencies include fencing, ungulate removal, and invasive weed control (USFWS, 2010; NPS, 2015; U.S. DOI, 1999).

State of Hawai'i

Approximately 61,162 ha (151,135 ac) of mesic forests occur on lands managed by the state of Hawai'i. They are found on all of the main Hawaiian Islands except Lāna'i (Fig. 11 and Table 6).

These native and nonnative forests are found within State Forest Reserves (FRS), parks, sanctuaries, and in Natural Area Reserves (NARS) (Table 4). The state forest reserves were created by the Territorial Government of Hawai'i in 1903 as early foresters recognized the need to protect forests to provide water for agriculture and surrounding communities. The Reserves encompass over 274,624 ha (678,611 ac) of land statewide. The Department of Land and Natural Resources (DLNR), Division of Forestry and Wildlife (DOFAW) manage the forest reserves and focus their resources on protection, management, restoration, and monitoring.

The Natural Area Reserves System (NARS) was established in 1970 with the intent to preserve in perpetuity native flora and fauna, as well as geological sites, of Hawai'i. The Natural Area Reserves are also administered by the DLNR, Division of Forestry and Wildlife (DOFAW). Lowland mesic forests are found within the Mt. Ka'ala and Pahole NAR on O'ahu and in the Ku'ia NAR on Kaua'i. Montane-mesic forests are found in the Ku'ia NAR on Kaua'i, Nakula NAR on Maui, and also in the Manuka NAR on the island of Hawai'i (Table 6). NARS management activities include construction of conservation fencing, ungulate management, weed control, and restoration of native species.

Department of Hawaiian Home Lands

The Department of Hawaiian Home Lands (DHHL) was created by the Hawai'i State Legislature in 1960 and is governed by the Hawaiian Homes Commission Act of 1920. The act set aside a land trust for native Hawaiians to maintain their traditional ties to the land. The primary responsibility of DHHL is to serve its beneficiaries and manage its land trust. DHHL also views its responsibility as a landowner to manage and protect native lands "to support both cultural and resource management activities and create homesteading opportunities for the future" (DHHL, 2009). Thus, the 'Āina Mauna Legacy Program was created to protect native forest on the slopes of Mauna Kea on the island of Hawai'i. The program specifically includes the lands of Humu'ula and Pi'ihonua, which contain tracts of mesic forest. Management goals include removal of invasive species, koa silviculture, native forest protection and restoration, conserving endangered species, and providing educational and cultural opportunities (DHHL, 2009).

Watershed partnerships

The Hawai'i Association of Watershed Partnerships (HAWP) comprises ten island-based statewide watershed partnerships that work collaboratively with more than 74 public and private partners on five islands to protect over 890,000 ha (2.2 million ac) of vital forested watershed lands (Hawai'i Association of Watershed Partnerships, 2018).

The HAWP's mission is to increase the effective management and protection of upper elevation watershed areas. Watershed partnerships undertaking conservation efforts to protect and manage large areas of mesic forest include the Three Mountain Alliance, Mauna Kea Watershed Alliance, East Maui Watershed Partnership, West Maui Watershed Partnership, Leeward Haleakalā Watershed Restoration Partnership, and East Moloka'i Watershed Partnership.

Safe harbor agreements

The Federal and State Safe Harbor programs encourage proactive conservation efforts by non-Federal landowners while providing them certainty that future property-use restrictions will not be imposed if those efforts attract species listed as endangered or threatened to their property, or result in increased populations of endangered or threatened species already present. In return for voluntary conservation commitments, the Agreement gives the landowner assurances covered by agency permits that allow for future alteration or modification of the enrolled property back to its original condition. These cooperative efforts provide landowners with a way to manage their lands to support the conservation of listed species while conducting approved land-use practices. Without this cooperative government/private effort, the private property would be less valuable to the recovery of endangered or threatened species (State BLNR, 2018).

A Safe Harbor Agreement between Kamehameha Schools, the State Department of Land and Natural Resources, and the U.S. Fish and Wildlife Service was finalized in June of 2018. The total area covered by the agreement is 13,034 ha (32,208 ac) on lands owned by Kamehameha Schools on the island of Hawai'i. The area covered by the SHA includes mesic forest resources. The 50-year agreement will contribute to the recovery of 32 endangered species and the agreement is part of an ongoing watershed partnership effort within the State of Hawai'i managed by the Three Mountain Alliance Watershed Partnership. Management activities covered by this agreement include outplanting of native plant species, control of invasive plants, koa silviculture, predator control, fencing and ungulate removal, fire threat management, response efforts to rapid 'Ōhi'a Death, and other land management activities that assist in the maintenance and enhancement of native forest (TMA, 2007; State BLNR, 2018; KS, 2014).

Pulama Lāna'i

The island of Lāna'i is privately owned but does have conservation partnerships with the U.S. Fish and Wildlife Service, the State of Hawai'i, and The Nature Conservancy. Currently the land manager, Pulamā Lāna'i, is implementing actions that benefit mesic forests inside its Lāna'ihale unit (Increments 1 and 2). The management unit encloses a total of 890 ha (2199 ac) and ongoing management actions within the unit include the control of invasive ungulates and weeds. Three smaller fenced units, totaling less than 6 ha (15 ac) have been constructed for the purposes of protecting individual rare plant and snail populations that occur in mesic forests (Lāna'i Resorts et al., 2015, in. litt.).

Invasive species committees

The Invasive Species Committees (ISC's) are voluntary island-based partnerships on Kaua'i (KISC), O'ahu (OISC), Maui (MISC), Moloka'i (MOMISC), and the Big Island (BIISC) that work with government agencies, nonprofit organizations, and private businesses and landowners to protect each island from the most threatening pests with a proactive approach. The ISC's target species that have high potential to severely impact the economy, environment, agriculture, human health, and quality of life (HDLNR, 2015).

Work done by these committees contributes directly to the conservation of mesic forests through removal and reduction of invasive plants and animals in mesic forests and in restoration of sites across the Hawaiian Islands. In addition, the ISC's helps generate public education that in turn enhances conservation of mesic forests.

Ranching and farming easements

Land eligible for agricultural easements that overlaps with the mesic forests are generally composed of rangeland, grassland, pastureland, and nonindustrial private forest land. The Natural Resources Conservation Service (NRCS) prioritizes the protection of agricultural uses and related conservation values of the land and those that maximize the protection of contiguous acres devoted

to agricultural use. Private landowners and lessees may enroll land through agricultural land easements through NRCS. Easements are contingent on the development of an agricultural land easement plan that promotes the long-term viability of the land (USDA, 2018). The Natural Resources Conservation Service currently have no dedicated land through such easements currently in the state of Hawai'i.

The NRCS Healthy Forests Reserve Program (HFRP) also helps landowners restore, enhance and protect forestland resources on private lands through easements and financial assistance. The HFRP aids the recovery of endangered and threatened species under the Endangered Species Act, improves plant and animal biodiversity, and enhances carbon sequestration (USDA, 2018).

The Healthy Forests program is not yet available in the NRCS-Pacific Islands Area (PIA). This program could assist landowners with mesic forest restoration and protection in the future.

Military

The United States Army has instituted an ecosystem management program to mitigate environmental impacts of their military training activities. This is an active and well-funded management program for native systems occurring within military managed lands. The United States Army and other military branches in Hawai'i also provide acquisition buffer programs that have played important roles in acquiring important threatened and endangered species habitat (State of Hawai'i DLNR, 2016). The O'ahu Army Natural Resources Program conducts research and conservation efforts in mesic forest areas to promote reduction in invasive species and reduce fire occurrence. These efforts collectively help to support conservation, restoration, and protection of native mesic forests across the main Hawaiian Islands.

Hawai'i Wildfire Management Organization

Since 2002, the Hawai'i Wildfire Management Organization (HWMO) has worked with communities throughout the state of Hawai'i to implement dozens of projects mitigating wildfire hazards and protecting natural and cultural resources. HWMO partners work closely with varied organizations from the United States Forest Service, United States Army, and University of Hawai'i, to the grassroots small community associations of Hawai'i's towns and villages. They sponsor community wildfire preparedness workshops, and have conducted wildfire hazard assessments for every community in the State. These assessments provide a more thorough understanding of wildfire hazards that can be addressed by communities, decision makers, fire responders, and natural resource managers. This organization directly supports the conservation of mesic forests through preparation and education efforts to minimize destruction of mesic forests by wildfires (HWMO, 2018, in litt.).

Others

Several groups have organized and taken action to address native species and ecosystem level conservation issues. The Hawaiian Forest Bird Recovery Team is an example where the group assisted in developing the Draft Revised Recovery Plan for Hawaiian Forest Birds that includes efforts to conserve and protect mesic forests where endangered populations of birds occur (Hawai'i Resource Strategy, 2010). The Maui forest bird recovery project has also undertaken large-scale forest restoration efforts in the mesic forest of the Nakula NAR on Maui.

Future Scenarios

The condition of Mesic Forests in the foreseeable future is based on potential changes in three conservation management parameters (CMPs). These conservation parameters capture the social and legal mechanisms under which natural resource conservation is carried out. The CMPs are as follows:

- (1) *Conservation values*: Stakeholder involvement and public opinion determine the formulation, implementation and funding of natural resource conservation within laws and development plans.
- (2) *Laws and biosecurity*: National, state, county, and city laws and regulations are the means by which natural resource conservation and biosecurity are supported and implemented (e.g., hunting regulations, Clean Water Act, Endangered Species Act, and local laws, etc.).
- (3) *Development or conservation planning*: National, state, county, city, and private development plans or conservation plans define specific actions that result in losses or gains in natural resource conservation and biosecurity (impacts are only realized at the time of implementation).

These conservation management parameters are critical factors that drive the direction and magnitude of natural resource conservation, and determine foreseeable future scenarios. The year 2035 is the extent of the "foreseeable future," and is based on the projected divergence of IPCC Representative Concentration Pathway (RCP) climate change scenarios (van Vuuren et al., 2011a,b; Miller 2018).

The four foreseeable future scenarios considered in this habitat assessment are:

- Future Scenario One, Status Quo*—The most likely foreseeable future; no change in natural resource conservation in the CMPs, so the current rate of change in land cover continues through the foreseeable future.
- Future Scenario Two*—A slight increase in natural resource conservation in the CMPs marginally improves conservation management.

Future Scenario Three—A slight to moderate decrease in conservation actions in the CMPs substantially decreases conservation management.

Future Scenario Four—A moderate to large increase in conservation actions in the CMPs substantially improves conservation management.

The future condition of Mesic Forests in Scenario One, the status quo, was characterized from an assessment of change over time in Mesic Forest land cover obtained from existing land cover maps (see [Amidon and Reeves 2018](#) for a description of land cover change assessment methodology.). Based on these land cover maps, an annual rate of change for Mesic Forests was estimated, and a projected change (in acres/ha) was calculated for the year 2035. The resulting information on changes in land cover by 2035, as derived from existing land cover change estimates, is the extent of the Mesic Forest ecotype that is expected in the foreseeable future under Scenario One, the status quo, where conservation efforts remain unchanged and the current rate of change in land cover is also unchanged ([Amidon and Reeves, 2018](#)).

The future conditions of Mesic Forests for Scenarios Two, Three, and Four cannot be quantitatively (acres/ha) estimated. However, the Scenario One estimate can provide a “baseline” for a qualitative characterization of changes in the future condition of Mesic Forests under Scenarios Two, Three, and Four.

Changes in human population are captured only by the changes in the “developed” land cover footprint derived from land cover map analysis ([Amidon and Reeves, 2018](#)). Impacts from other sources of human activities or human-caused habitat stressors (e.g., plant and animal diseases, wildfires, invasive species, etc.) are not well characterized in the land cover changes, but significantly contribute to increases in the land cover area dominated by nonnative vegetation. For an assessment of island-by-island changes in human population see [Amidon and Reeves, 2018](#).

Also, note that island-wide implementation of the CMPs is unlikely to have a significant effect on climate-related stressors (temperature, precipitation, and severe weather) resulting from global warming by 2035. This lack of CMP climate effects is due to the global lag in climate response to changes in greenhouse gas emissions which occurs on the order of centuries rather than years ([Solomon et al., 2009](#); [Gillett et al., 2011](#); [Jevrejeva et al., 2012](#)). Evidence of climate effects is also confounded by the large annual variation in the Pacific islands climate parameters, which is much greater than projected climate change by 2035. Although impacts from climate-related habitat stressors do not change across the four scenarios, they were included in this analysis because of their overall magnitude of potential importance to future habitat viability.

Future Scenario One—Status Quo

Summary: Under Scenario One there is no anticipated change in the implementation of the three CMPs between 2018 and 2035. A continuing current rate of change in land cover through this foreseeable future results in a slow but continuous change in mesic forest subcategories ([Table 8](#)).

Native mesic forests would have a continued decline in size and distribution, and therefore a decrease in redundancy. Human-caused stressors will have a small increase overall and continue to reduce the size and quality of native mesic forests. Ecological function is predicted to be reduced due to the ability of invasive plants and animals to outcompete native plants for water and space, subsequently resulting in a reduction in native biodiversity. Degradation of native mesic forests will continue to increase as remaining areas become more fragmented, thus reducing their resiliency and representation.

Introduced mesic forests are predicted to increase in size and distribution (redundancy) as a result of the overall small increase in human-caused ecotype stressors. Introduced mesic forests are likely to expand as invasive species replace native-dominated communities, resulting in an increase in their resiliency, redundancy, and representation ([Table 9](#)).

The managed tree plantations are predicted to increase in size and distribution due to the assumed expansion of the human population and continued development pressure for forest products (lumber, fuel), horticulture, and agriculture (coffee, fruit, nut orchards) resulting in an increase in their resiliency, redundancy, and representation ([Table 9](#)).

Future Scenario Two

There is a slight increase in the CMPs that marginally improves conservation management.

Conservation agencies and stakeholders work with increased but limited resources to slow or stop the degradation of native mesic forest areas. Introduced mesic forests will continue to increase. Scenario Two is essentially “status quo” with minor improvements in the three CMPs. This scenario is expected to have the second highest likelihood of occurring into the foreseeable future, being slightly less likely than Scenario One ([Table 9](#)).

Future Scenario Three

There is a small to moderate decrease in conservation actions in the CMPs that substantially decreases conservation management.

All natural resource management actions in the CMPs are set aside in deference to land use for economic development. With extensive localized management, some native species may persist in park-like settings or in areas where land development is not possible. This scenario has substantial declines in natural resource conservation within the three CMPs. An increasing human population is supported in its use of land for economic development over the conservation of native ecotypes. Areas that cannot

Table 8 Responses of mesic forest habitat stressors in foreseeable future scenarios (Amidon and Reeves, 2018).

Conservation management parameters (CMPs)				
Conservation values	Stakeholder involvement and public opinion influence the formulation, implementation, and funding of natural resource conservation and biosecurity (NRC/B) within laws and development or conservation plans			
Laws and biosecurity	National, state, county, and city laws and regulations are the means by which NRC/B are supported and implemented			
Planning for development or conservation	National, state, county, city, and private development plans or conservation plans define actions that result in losses or gains in NRC/B (impacts realized at implementation)			
Foreseeable future scenarios and the resulting mesic forest conditions				
Use foreseeable future Scenario One as a “baseline” to characterize changes in <i>Conservation Actions</i> and mesic forest <i>Conditions</i> in future Scenarios Two, Three, and four	Scenario One: <i>CMPs</i> : unchanged in support for NRC/B <i>Conservation actions</i> : no change; current rate of land cover change continues through the foreseeable future <i>Mesic forest condition</i> : ecotype area, quality, and sustainability slowly decrease through the foreseeable future	Scenario Two: <i>CMPs</i> : small increase in support for NRC/B <i>Conservation actions</i> : marginal increase. <i>Mesic forest condition</i> : ecotype area is unchanged through the foreseeable future; habitat quality and sustainability are slightly enhanced through the foreseeable future	Scenario Three: <i>CMPs</i> : small to moderate decrease in support for NRC/B <i>Conservation actions</i> : substantial decrease <i>Mesic forest condition</i> : urban and agricultural uses are prioritized over conservation; ecotype area, quality, and sustainability substantially decrease through the foreseeable future	Scenario Four: <i>CMPs</i> : moderate to large increase in support for NRC/B <i>Conservation actions</i> : substantial increase <i>Mesic forest condition</i> : robust, sustained effort to restore, manage, and expand conservation; ecotype area, quality, and sustainability substantially increase through the foreseeable future
Stressors	Responses of mesic forest stressors			
Development	Small to moderate increase	No change (redevelop)	Moderate to large increase	Small to moderate decrease
Altered hydrology	No change to small increase	No change	Larger increase	Small decrease
Recreation/access	Small increase	Small increase	Larger increase	Larger increase
Invasive species	Small increase	Small increase	Larger increase	Small decrease
Plant diseases	Small increase	Small increase	Larger increase	No change to small decrease
Fire	Small increase	Small increase	Larger increase	No change to small increase
Erosion	Small increase	No change	Larger increase	Small decrease
Climate

Precipitation	Small decrease	Small decrease	Small decrease	Small decrease
Storms	Small increase	Small increase	Small increase	Small increase

Table 9 Summary of overall condition for mesic forest biome subtypes in the future scenarios.

<i>Mesic forest subtype</i>	<i>Scenario One: status quo</i>	<i>Scenario Two: slightly improved</i>	<i>Scenario Three: substantially decreased</i>	<i>Scenario Four: substantially improved</i>
Montane-subalpine mesic forest	Decrease	Slowly decrease	Decrease	Significantly increase
Lowland mesic forest	Decrease	Slowly decrease	Decrease	Significantly increase
Introduced mesic managed tree plantation	Increase	Slightly increase	Significantly increase	Slowly decrease
Hawai'i introduced wet-mesic forest	Increase	Slightly increase	Significantly increase	Slowly decrease

support development become the only areas of free-living native species. The anticipated changes, under Scenario Three, for each of the ecotype stressors important to Mesic Forests are given in [Table 8](#).

Overall, this scenario would severely degrade and fragment native mesic forest habitat and result in their reduced resiliency, redundancy, and representation. Introduced mesic forest subtypes would significantly increase in resiliency, redundancy, and representation under this scenario. This scenario, along with Scenario Four, has the lowest likelihood of occurring in the foreseeable future ([Table 9](#)).

Future Scenario Four

There is a moderate to large increase in conservation actions in the CMPs that substantially improves conservation management.

For this scenario, substantial improvements to the three CMPs and a general decrease in human-caused ecotype stressors would increase the size and quality (resiliency) of native lowland mesic forests and montane-subalpine mesic forests. Although this

increase in native forest sub-types would be gradual at first it will become more noticeable by 2035 as the substantial improvements to the three CMPs will help keep these subtypes from declining. The introduced mesic forest subtypes would slowly decrease in resiliency, redundancy, and representation under this scenario (Table 9).

Based on this analysis, the substantial improvements in restoration for native mesic forest ecotypes would result in increased resiliency, redundancy, and representation and introduced subtypes would slowly decrease. This scenario, and Scenario Three have the lowest likelihood of occurring in the foreseeable future.

Conservation Implications

Under the most likely future scenario, the native mesic forests are expected to decrease in resiliency, redundancy and representation while the introduced subtypes are predicted to increase (Tables 9 and 10). Conservation efforts by Federal, State, private, and multiple agency partnerships have been beneficial in helping to conserve and protect native mesic forests. Without increased effort the current level of conservation is insufficient to conserve the native subtypes of this biome. The continued spread of invasive plants and browsing ungulates is rapidly degrading native dominated mesic forests decreasing their resiliency and representation while the introduced subtypes continue to increase (Table 10). The managed tree plantations are also increasing in representation, redundancy and resiliency as interest in tree plantations for forest products (lumber and fuel) grows (Landfire, 2016). Additionally, the loss of marine derived nutrients from seabirds, insect pollinators, and seed dispersing native birds, adds to a decrease in resiliency of the native forest subtypes. All of these impacts combined with changes in fire regime, climate, and water availability are more favorable to the introduced mesic forest subtypes than they are to the native mesic forests which are decreasing in resiliency, representation, and redundancy (Table 10).

Mesic Forests Conclusion

In summary, the conservation efforts by Federal, State, private, and multiple agency partnerships have been beneficial in helping to conserve and protect the remaining mesic forests in Hawai'i. The protection and restoration of mesic forests cannot be accomplished solely on Federal lands however, because their range occurs primarily on non-Federal lands. To achieve conservation objectives these non-Federal mesic forests require cooperative conservation efforts on private and State lands. Increasing funding sources remains a high priority, to accomplish the goals of expanding and actively managing the remaining mesic forests.

The primary stressors to mesic forests include habitat destruction and modification by invasive ungulates, competition with invasive plant species, insects, forest disease, natural disasters (storms, landslides hurricanes), fire, drought, agriculture and urban development, and climate change. These stressors act in concert with other stressors on mesic forests, and are expected to continue or increase in magnitude and intensity in the future without effective management actions to ameliorate threats.

Finally, the condition of mesic forests in the foreseeable future favors Scenario One, which has the highest likelihood of occurring in the foreseeable future relative to the other scenarios. Under Scenario One there is no change in the implementation of the conservation management parameters (CMPs). Scenario Two is based on a slight increase in the implementation of the CMPs, which marginally improves conservation management. Thus Scenario Two is expected to have the second highest likelihood of occurring into the foreseeable future, being slightly less likely than Scenario One. Scenario Three is based on a slight to moderate decrease in conservation actions in the CMPs which substantially decreases conservation management. Because there is a decrease in the implementation of the CMPs, Scenario Three would severely degrade and fragment native mesic forest eco-types and result in reduced resiliency, redundancy, and representation. In Scenario Four, the substantial improvements in restoration for native mesic forest eco-types would result in increased resiliency, redundancy, and representation. However, this scenario and Scenario Three have the lowest likelihood of occurring in the foreseeable future.

Overall, the CMPs are critical factors that drive the direction and magnitude of natural resource conservation and determine the foreseeable future scenarios. Any increase in the implementation of the CMPs will result in the greatest conservation returns for native mesic forest (Scenario's Two and Four). Conversely, any decrease in the implementation of the CMPs will result in the least conservation returns for native mesic forest (Scenario's One and Three). Thus, realistic expectations of the implementation of the CMPs were considered when determining the likelihood of occurrence for each scenario in the foreseeable future.

Table 10 Summary of interactions of current stressors and conservation efforts on redundancy, resiliency, and representation in the mesic forest subtypes.

<i>Mesic forest biome subtype</i>	<i>Redundancy</i>	<i>Resiliency</i>	<i>Representation</i>
Introduced mesic managed tree plantation	Increase	Increase	Increase
Introduced wet-mesic forest	Increase	Increase	Increase
Lowland mesic forest	Decrease	Decrease	Decrease
Montane-subalpine mesic forest	Decrease	Decrease	Decrease

Abstract

We present a status assessment of the Mariana Islands archipelago (Marianas) forests, including the current status, stressors, and future viability. Forests in the Marianas generally receive moderate to high rainfall during distinct wet and dry seasons

and are associated with limestone or volcanic substrates. Prior to the arrival of humans in the Marianas approximately four centuries ago, native forest was the dominant forest type. As a result of natural and anthropogenic disturbance, a proportion of native forest was converted to three additional forest sub-types: secondary, monoculture, and *Leucaena* forests. Forests were defined and characterized using the classification of landcover types for the Mariana archipelago developed by Amidon et al. (2017). Currently, forests occur on all islands in the archipelago, except for Farallon de Medinilla due to extensive bombing during military operations and continuing volcanic activity on Uracas. The main stressors to forests are invasive species, development, volcanic eruptions, typhoons, and fire. Ongoing conservation efforts include biosecurity measures, protected area and species management, invasive species control, and existing laws and regulations. Forest viability, defined as the likelihood of persistence over the long term, is described based on the concepts of representation, redundancy, and resiliency. We developed four plausible future scenarios, each differing in levels of natural resource management, to evaluate the status of forests into the foreseeable future. Two of the scenarios, which are based on no change in conservation actions (Scenario One; status quo) and a slight increase in conservation actions (Scenario Two) have the highest likelihood of occurring in the foreseeable future while the other two, which are based on a slight to moderate decrease in conservation actions (Scenario Three) and a moderate to large increase in conservation actions (Scenario Four) do not. Scenario One would continue to degrade and fragment native forests and result in reduced resiliency, redundancy, and representation. In Scenario Two, the slight improvements in conservation actions would result in a moderate increases in resiliency, redundancy, and representation.

Mariana Islands Forest

Introduction

The Mariana archipelago consists of 15 main islands and various small islets spanning a north-south distance of 890 kilometers (km) in the western Pacific Ocean between latitudes 21° and 13°N and longitudes 144° and 146°E. The vast majority of the archipelago's land area is concentrated in the larger, southern main islands, including Saipan, Tinian, Rota, and Guam.

We provide an overview of the forest ecoregion in the Mariana archipelago and describe the ecological factors that have influenced this biome over time and into the future. Forests occur on all islands in the archipelago, except for Farallon de Medinilla due to extensive bombing during ongoing military operations and continuing volcanic activity of Uracas. A thorough introduction of the geography, geology, climate, hydrology and descriptions of the islands in the Marianas archipelago are described in the chapter on Physical Geography of the Mariana Archipelago by Harrington in this work.

Description

Here we use the definition of a forest as a plant community characterized by vegetation with >25% cover in trees (a woody perennial that usually has a single trunk) (Gagne and Cuddihy, 1999). We defined and characterized Mariana forests using the landcover types for the Mariana archipelago described by Amidon et al. (2017). The 2017 study incorporated existing classification systems by the National Oceanic and Atmospheric Administration (NOAA) and U.S. Forest Service (Liu and Fisher, 2006a,b; NOAA, 2017) with additional imagery data to delineate a total of 23 vegetation types in six major landcover types (biomes). Ten vegetation types associated with the forest biome were then grouped into the four Marianas forest sub-types: native, secondary/mixed, monoculture, and *Leucaena leucocephala* or tangantangan, hereafter referred to as "*Leucaena*" described in the Current Condition section.

Geology

The six southern islands are geologically older than the nine northern islands, and due to complex plate uplifting, contain large areas of limestone substrate and areas volcanic in origin. The islands are characterized by plateaus ringed by a series of steep escarpments (Young, 1989). Limestone areas have shallow, highly weathered soils with an abundance of calcium (Donnegan et al., 2011). Guam, Rota, Aguiguan, Tinian, and Saipan exhibit well-developed, deep soils where the underlying volcanic parent materials have been exposed and weathered. The abundance of calcium in the limestone and coral sand on these landscapes creates soils that are inherently more fertile than volcanic soils (Donnegan et al., 2011).

All of the northern islands, from Anatahan to Uracas, are stratovolcanoes comprised mostly of hardened lava, tephra and volcanic ash, and are characterized by steeply sloping topography, both above and below the ocean's surface (Brainard et al., 2012). Periodic, explosive volcanic eruptions occur on the islands, with the most recent major eruptions occurring at Uracas in 1967, Pagan in 1981, and Anatahan in 2003 (Global Volcanism Program, 2013). While deep, soil developed on volcanic parent materials has low fertility, most of which resides in the topsoil.

Physical/life history components

Water availability and climate

Climate in the Mariana archipelago is classified as "tropical rainforest" (according to the Koeppen climate classification) with seasonal monsoons (Ohba, 1994). Moderate temperatures, ranging between 30 °C and 22.8 °C and constant trade winds create stable conditions. Precipitation averages 96 in (218 cm) per year, dependent in part on elevation, with a rainy season between July and October, and a drier season from November through June, with April characteristically being the driest month of the year (Ohba, 1994; Mueller-Dombois and Fosberg, 1998). During the dry season, brisk east and northeast trade winds dominate

the western Pacific Ocean (Eldredge, 1983), while slower east and southeast trade winds occur during summer months. An average of at least one tropical cyclone per year impacts the Mariana archipelago, typically during the summer months as they move from east to west.

Vegetation structure and composition

Forests in the Marianas are characterized by a closed canopy of broadleaf trees with an understory of younger trees, vines, epiphytic ferns, and orchids (Stone, 1970; Vogt and Williams, 2004). It is usually composed of tall trees (10+ meters (m)) that comprise the upper canopy, small to mid-size trees (3–10 m) as a mid-story, and shrubs and herbs that form the understory (Falanruw et al., 1989a,b). Undergrowth can be sparse in densely shaded areas but may contain ground herbs, shrubs, ferns, and small trees of varying heights in areas with more open canopy.

The Marianas are one of the highest risk areas in the world for typhoons (Marler, 2001). Many plant species evolved to avoid catastrophic damage from these storm events by having leaves which are easily removed during high wind. This is far less damaging than uprooting or the breaking of major branches. Most native woody perennial plants recover fairly rapidly following typhoon damage, provided that they remain well-rooted and the major scaffold system of the canopy remains intact (Marler, 2001).

Biodiversity/biotic components

The Marianas, situated in Micronesia, lies within the Polynesia-Micronesia bioregion recognized as a global biodiversity hotspot (Conservation International, 2019). A comprehensive study of the endemic plant species in Micronesia indicate that the region contains the highest percentage of plant endemism per kilometer out of globally recognized insular biodiversity hotspots (Costion and Lorence, 2012). The combination of old age and close proximity to continental land masses of some of the Micronesian islands has enabled them to accumulate a very high richness of distinct plant lineages compared to more remote archipelagos such as Hawaii. The Marianas possess a level of richness measured by endemic plants per square kilometer (5%; 54 endemics/1007 total species) somewhat below the average for the region (14%; 364/2628), but on par with other island groups recognized for their biodiversity (Hawaii at 4%, Fiji and Samoa at 5%, and Marquesas and Society Islands at 6%).

Forests in the Marianas provide habitat for several endemic vertebrate species including the Mariana fruit bat (*Pteropus mariannus mariannus*), Micronesian megapode (*Megapodius laperouse*), and the Mariana crow (*Corvus kubayari*). Many of these native vertebrate species are known to be important pollinators and/or dispersers of seeds for the native forest plant species. Without seed dispersing vertebrates, plants would deposit their seeds directly below themselves with little expectation of successful reproduction due to low light, competition with more established plants and high seed density.

Several endemic invertebrate species such as the fragile tree snail (*Samoa fragilis*), humped tree snail (*Partula gibba*) and Guam tree snail (*Partula radiolata*) occur in the cool, shaded forest habitat with high humidity and reduced air movement (USFWS, 2015a). These invertebrates feed primarily on dead or decaying plant material recycling nutrients near the bottom of the food chain (Cowie, 1992). This recycling creates chemical nutrients that are released back into the soil, air and water and become available for new growth.

Pre-Human Condition

Forest Sub-types

Marianas forests likely began as strand vegetation (small plants that hold the soil and are tolerant of wind, salty air, and waves) that dispersed from elsewhere to isolated shores via the sea, and inland plant species blown by air currents to the islands' slopes and mountains. These initial plant species evolved to create distinct species adapted for newly encountered niches including the limestone substrate. In addition, seed dispersers such as bats or migrating birds are likely responsible for carrying some species to the islands, and during the evolution of the plant fauna, new species were continually making their way to the island chain (Berger et al., 2005).

Before human settlement occurred on the Marianas, forests had probably reached their climax of primary succession. Forested areas were likely well distributed on the southern islands of Guam, Rota, Aguiguan, Tinian, Saipan, and Farallon de Medinilla, and likely covered the majority of the landmass (Reeves and Amidon, 2018). Conversely, the northern islands are much younger geologically, and many have large areas of barren lava or lack the kind of soils needed to support forests (Ohba, 1994). The species found in the pre-human forest in the southern islands included, but were not limited to: *Ficus*, *Elaeocarpus*, *Mammea*, *Guamia*, *Cynometra*, *Aglaia*, *Premna*, *Pisonia*, *Ochrosia*, *Neisosperma*, *Intsia*, *Melanolepis*, *Eugenia*, *Pandanus*, *Artocarpus*, *Hernandia*, and others (Engbring et al., 1986). In the native forest found on the northern islands, predominant plant genera included *Aglaia*, *Pandanus*, *Terminalia*, *Trema*, *Morinda*, and *Erythrina* (Liske-Clark, 2015). Several of the trees and shrubs within these groups, including *Artocarpus mariannensis*, *Pandanus tectorius*, and *Terminalia catappa* are endemic or indigenous and produce fruit that provide food for wildlife such as the Mariana fruit bat (Vogt and Williams, 2004).

Forest Viability of Pre-Human Conditions

The viability of Mariana forests depended on maintaining multiple and distributed occurrences (redundancy) of sufficient quality and size (resiliency) with species richness and genetic diversity (representation) to survive across the Mariana archipelago over time.

Native forests likely recovered quickly from storms and were widespread across many islands and appeared to be well-represented. The ecologically healthy, or viable, forests that existed throughout the Marianas prior to human contact likely maintained natural connections between system components. Native biota that was historically characteristic of Mariana forests filled environmental niches necessary to sustain the habitat. It can be assumed that in the less volcanically active southern islands, forests reached their carrying capacity and were spread across the islands with a high level of land coverage. Conversely, in the northern volcanic islands, the frequency and intensity of volcanic eruptions likely had catastrophic impacts to forest vegetation and replaced suitable soils with volcanic rocks which made it difficult for new forest plants to colonize. This delayed or prevented succession into native forest as seen on areas of all of the northern islands.

Reproductive strategies of forest species, such as fruit and seed dispersal by birds and fruit bats, encouraged representation on all islands that supported those dispersing species. In addition, the presence of fruit-eating animals such as birds and fruit bats benefited plant recruitment by increasing germination during gut passage and moving seeds away from conspecifics, thereby creating more resilient forest systems (Egerer et al., 2018). Overall, the high diversity of plant species and seed dispersers within native forests in the Marianas likely improved the ability of these forests as a whole to survive stochastic or even catastrophic events.

Table 1 summarizes the viability of Mariana forests in its pre-human condition based on what is known about these forests in their native state.

Current Condition

Forest Sub-types

Prior to the arrival of humans approximately four centuries ago, native forest was the dominant forest type in the Marianas. As a result of natural and anthropogenic disturbance, a proportion of native forest was converted to three additional forest sub-types: secondary, monoculture, and *Leucaena* forests. A summary of current Mariana forest sub-types, dominant canopy species, and distribution across the archipelago follows in **Table 2** (Fig. 1).

Current Forest Extent/Range

Native forest

In its current condition, native forest covers approximately 38,288 ac (15,495 ha) or 15% of the land area in the Marianas (Reeves and Amidon, 2018). In the southern islands, native forest is predominantly restricted to limestone substrate (25,347 ac (10,258 ha)) with the exception of native volcanic forest on Guam (8576 ac (3471 ha)). In the northern islands, native forest is represented only by volcanic forest (3542 ac (1433 ha)) and hibiscus thicket (590 ac (239 ha)). The impacts of nonnative species and human colonization have greatly influenced the quality and quantity of native forests throughout a majority of the archipelago. Only the islands of Guguan, Asuncion, Uracas, and Maug have been left relatively undisturbed, however relatively recent volcanic eruptions has limited the amount of native forest established on these islands.

Southern Islands

Approximately 90% (13,821 ha) of native forest can be found in the southern islands with the most area on Guam (8769 ha) and Rota (4068 ha), followed by Tinian (432 ha), Aguiguan (380 ha), and Saipan (173 ha). Native forest represents a significant portion of the islands of Rota (47%) and Aguiguan (55%), but less than 17% of Guam, less than 5% of Tinian and 2% of Saipan. The decline in the quantity of native forests on Guam, Tinian, and Saipan largely occurred from clearing for agriculture, residential, commercial and military development (Liske-Clark, 2015; USFWS, 2015a,b). Nevertheless, native forest still occurs along the edges and tops of cliff sides, in steep ravines, and other rugged karst terrain.

Although Rota and Aguiguan still contain large tracts of native forest, the high number of feral ungulates on both islands impedes recruitment of native plants by browsing on new growth and seedlings. The reduction in new growth and recruitment makes the native forests on these islands less able to recover from stochastic and catastrophic events (decreased resiliency and redundancy). The introduction of the brown tree snake had a profound effect on the forests of Guam by preying on and completely wiping out a majority of the forest birds on the island, which served as important pollinators and seed dispersers for the forests. Some native forest seeds need to pass through the gut of a bird to germinate, therefore islands with healthy bird populations (Rota, Tinian, and Saipan) have more intact forests than Guam (Rogers, 2011). A decline in fruit bat populations may have had an impact on the recruitment of forest trees with large seeds such as *Cycas micronesica*. Feral pigs and deer have also been found to act as seed dispersers, although feral ungulates have been found to selectively disperse native species (Gawel et al., 2018).

Table 1 Assessment of native forest resiliency, redundancy, and representation of forests in the Mariana Islands prior to human contact.

Forest type	Resiliency	Redundancy	Representation
Native forest	High	High	High

Table 2 Mariana archipelago forest subtypes with associated vegetation types, dominant species, and brief descriptions (Amidon et al., 2017; Reeves and Amidon, 2018).

Forest subtype	Vegetation Types	Dominant species (Common name)	Characteristics	Island															
				Agr	Agu	Ala	Ana	Asu	FDM	Gua	Gug	Mau	Pag	Rot	Sai	Sar	Tin	Ura	
Native	Native Limestone Forest	Canopy species include: <i>Elaeocarpus joga</i> (joga), <i>Pisonia grandis</i> (umumu or umomo), <i>Hernandia labyrinthica</i> (oschal), <i>Hernandia sonora</i> (nonak or nonag), <i>Ficus prolixa</i> (nunu), <i>Macaranga thompsonii</i> (pengua), and <i>Intsia bijuga</i> (ifit)	Forest on limestone substrate with a canopy dominated by native tree species. Includes forests of varying age classes. Dominant canopy species can vary by island and region of island.																
	Native Volcanic Forest	Canopy species include: <i>Pisonia grandis</i> (umumu or umomo), <i>Hernandia sonora</i> (nonak or nonag), <i>Barringtonia asiatica</i> (putting), <i>Pandanus tectorius</i> (kafu), and <i>Terminalia catappa</i> (talisai).	Forest on volcanic soil substrate with a canopy dominated by native tree species. Includes forests of varying age classes and is primarily found in the northern volcanic islands of the CNMI and volcanic soil regions of southern Guam.																
	Hibiscus Thicket	<i>Hibicus tiliaceus</i> (pago)	Found throughout the archipelago around wetlands, along streams, and in interior areas																
Secondary	Mixed Introduced Forest	Canopy species can include combinations of coconut, ironwood, tangantangan, <i>Spathodea campanulata</i> (African tulip tree), <i>Delonix regia</i> (flame tree), <i>Acacia confusa</i> (sosugi), <i>Albizia lebbbeck</i> (trongkon-kalaskas), <i>Pithecellobium dulce</i> (kamachile), and <i>Samanea saman</i> (trongkon-mames or monkeypod)	All forests dominated by non-native species. May include components of other forest subtypes. Mixed in composition, not dominated by a specific non-native species.																
	Vitex Forest	<i>Vitex parviflora</i>	Large stands occur in northern Guam																

(Continued)

Table 2 Mariana archipelago forest subtypes with associated vegetation types, dominant species, and brief descriptions (Amidon et al., 2017; Reeves and Amidon, 2018).—cont'd

Forest subtype	Vegetation Types	Dominant species (Common name)	Characteristics	Island														
				Agr	Agu	Ala	Ana	Asu	FDM	Gua	Gug	Mau	Pag	Rot	Sai	Sar	Tin	Ura
Monoculture	Coconut Forest	<i>Cocos nucifera</i> (coconut)	Former coconut plantations. Found on limestone and volcanic substrates.															
	Casuarina Forest	<i>Casuarina equisetifolia</i> (ironwood)	Along shorelines and throughout the interior of an island. Found on volcanic and limestone substrates.															
	Bamboo Thicket	<i>Bambusa vulgaris</i> (bamboo)	Along streams and near wetlands, however, can also occur throughout the interior of an island.															
	Acacia Forest	<i>Acacia auriculiformis</i> and <i>Acacia mangium</i>	Found on volcanic substrates in the badlands on southern Guam.															
Leucaena	Leucaena Thicket	<i>Leucaena leucocephala</i> (tangantangan)	Associated with previously cleared areas and often forms monotypic stands. Found on limestone and volcanic substrates.															

Shading indicates occurrence of forest.

Guam, Mariana Islands

Rota, Mariana Islands

Fig. 1 (A–F) Current distribution of forests in the Mariana archipelago (Reeves and Amidon, 2018).

Tinian and Saipan, Mariana Islands

Fig. 1 (continued).

There are now several nonnative tree, shrub, and vine species that are found in native forests that colonize the forest edge and become established in disturbed areas. The colonization of these plants into the native forests has reduced the habitat quality and converted large swaths of the native forests in the islands most disturbed by humans further reducing resilience and redundancy of native forests (Figs. 2 and 3).

Northern Islands

Approximately 10% of native forest (1672 ha) in the Marianas can be found in the northern islands, comprised of 1433 ha of volcanic forest and 239 ha of hibiscus thicket. Native forest distribution, abundance, and quality varies among the northern islands largely based on the level of impacts from feral ungulates, copra production, and volcanic activity. Forests on islands such as Anatahan, Sarigan, Alamagan, Pagan, and Agrihan have been greatly affected by the introduction of ungulates. The recent volcanic eruptions on Anatahan and Pagan resulted in the loss of large tracts of native forest. Guguan, Asuncion and Maug did not have ungulates introduced and remain relatively unaffected by volcanism as well leaving their forests relatively intact.

Secondary forest

Secondary forest presently covers approximately 21,231 ha or 21% of the land area in the Marianas (Reeves and Amidon, 2018). Secondary forest is one of the most common forest types on the more developed southern islands such as Guam, Tinian, and Saipan due to a history of disturbance by humans. Aguiguan, Rota, and some of the northern islands (Anatahan, Alamagan, and Pagan), have smaller areas of secondary forest, while the islands that were not colonized by humans have little to none.

Secondary forest is composed of a mixture of native and nonnative species representing forests recovering from disturbance; native forests invaded by nonnative species or forests that are establishing in disturbed areas from a mix of seed sources (Liske-Clark, 2015). As such, secondary forests are generally dominated by nonnative species, but may include components of other forest types. Natural disturbances such as typhoons or drought can result in the loss of mature trees but the understory often remains intact, while man made disturbances such as land clearing and fire usually result in conversion to bare ground. During World War II, large portions of Guam, Tinian, and Saipan were destroyed during intense bombing or cleared for the development of military infrastructure. This resulted in major losses to native forest. Following disturbance, hardy and low-growing grasses and herbs colonized this bare ground. In time, shrubs, small trees, and seedlings of tall forest trees grow and soon overtop the grasses and herbs, forming a secondary forest. Major forest loss during World War II, and the introduction of nonnative plant species which outcompete natives led to the establishment of secondary forest currently found on large portions of Guam, Tinian, and Saipan.

Secondary forest tends to have a more open canopy, generally below 10 m in height, and a dense understory. Secondary forest is often composed trees such as *Albizia lebbbeck*, *Cynometra ramiflora*, *Ficus prolixa*, and a thick understory of native and introduced shrubs, vines, and grasses (Falanruw et al., 1989a,b) (Figs. 4 and 5).

Monoculture forest

Monoculture forest presently covers approximately 4688 ha or 5% of the land area in the Marianas (Reeves and Amidon, 2018). Monoculture forests are described as those planted by people for agricultural purposes or areas solely consisting of ironwood trees (*Casuarina equisetifolia*). Historically, large plantations of coconuts, for copra production (kernel of the coconut where oil is extracted), were planted and managed on several islands, including Anatahan, Sarigan, Alamagan, and Agrihan until the 1940s. It is likely that all areas of coconut monocultures were man-made, and not formed by coconuts being washed ashore in great numbers (Mueller-Dombois and Fosberg, 1998). In addition to coconut monoculture forests, mango (*Mangifera*), betel nut (*Areca catechu*), and citrus (*Citrus* sp.) monoculture forests are found on the islands where larger human populations exist such as Guam, Rota, Tinian, and Saipan. In these forests, the trees tend to all be the same height, as they were usually planted at the same time, and in rows. If the farm is actively being worked, the understory will typically be solely small herbaceous plants and grasses. The ground within coconut plantations is often filled with thick cordlike roots that prevent most other large woody plant species from growing (Mueller-Dombois and Fosberg, 1998).

In addition to agricultural monoculture forest, other monoculture forests in the Marianas exist because of allelopathic properties of certain species of trees such as ironwood (*Casuarina equisetifolia*). The long needle shaped leaves cover the forest floor, smothering

Fig. 4 Secondary forest vegetation summary with land cover types (Reeves and Amidon, 2018).

Fig. 5 Secondary forest in Navy Hill, Saipan. Photo credit: Tyler Willsey.

other plants, and have been found to have allelopathic tendencies to prevent other species' seeds from germinating (Wheeler et al., 2011). An ironwood forest typically has a single tree species and very limited understory. Currently, large expanses of iron wood monoculture forest occur on the islands of Guam, Tinian, and Pagan (Figs. 6 and 7).

Leucaena forest

Leucaena or tangantangan (*Leucaena leucocephala*) forest presently covers approximately 7768 ha or 8% of the land area in the Marianas (Reeves and Amidon, 2018). The southern islands of Guam, Tinian, and Saipan have vast areas of *Leucaena* forest, while

Fig. 6 Monoculture forest vegetation summary with land cover types (Reeves and Amidon, 2018).

Fig. 7 Betel nut (*Areca catechu*) monoculture forest on the island of Saipan. Photo credit Tyler Willsey.

Rota and Aguiguan only have a few stands (Vogt and Williams, 2004). *Leucaena* was not introduced to the northern islands so *Leucaena* forests do not exist north of Saipan. *Leucaena* was first observed on Tinian in 1946, although it is uncertain exactly when and how *Leucaena* was introduced to the Marianas and Tinian or whether it was intentional or inadvertent (Fosberg, 1980, unpublished report, as quoted in Hawaiian Agronomics 1985). It is possible that the U.S. military broadcast seeds of *Leucaena* and other plants from planes in an attempt to reduce erosion (Guam Division of Aquatic and Wildlife Resources (DAWR), 2006, Marler and Moore, 2011). Because of its rapid growth, and possibly allelochemical attributes (the ability to inhibit surrounding, competing plant growth) once established, it quickly forms dense thickets that crowd out native vegetation (Little and Skolmen, 1989). Consequently, *Leucaena* is considered highly invasive in many parts of the world including in the tropical Pacific

and the Hawaiian Islands. On some islands, *Leucaena* has formed large areas of dense forest which, due to its small leaves which allow bright sunlight to reach the forest floor, produces a xeric (containing little moisture) understory (Hopper and Smith, 1992) (Figs. 8 and 9).

Stressors

Historic Habitat Loss and Destruction

Since the arrival of humans in the Mariana archipelago, there has been ongoing degradation and impacts to native forests from hundreds of nonnative plants and animals, resulting in various rates of conversion to secondary, monoculture, and *Leucaena* forests in many areas. Archeological excavations indicate aboriginal human populations, including the Chamorro peoples, arrived in Micronesia 2000–4000 years ago and initiated major alterations to the native forests through a variety of activities such as the clearing of lands for agriculture. The human population during this initial period was relatively high compared to the islands' populations today and may have reached 20,000 on Tinian alone (Farrell, 1992). Studies of the pollen record strongly suggest human activities had transformed native forest into savanna over broad areas of the interior upland areas of Guam as early as 2000 years ago (Athens and Ward, 2004).

The arrival of Europeans in the 16th century also caused widespread damage to the forests. Reports from the 1700s indicate that Tinian's original forests were largely destroyed during early efforts to develop cattle ranching (Fosberg, 1960; Barratt, 1988). Later, during the 18th century, Spanish governors depopulated residents from the island to maintain it as a large pasture for cattle used to supply meat to the Guam garrison (Farrell, 1992).

During the German occupation of the Marianas from 1899 to 1917, native forest on several islands was converted to copra (*Cocos nucifera*) production. Several of the northern islands including Anatahan, Sarigan, Alamagan, Pagan, and Agrihan were likely dominated by native forests, but much of the lower coastal slopes were converted to copra plantations during this time (Spoehr, 1957). Extensive copra plantations likely existed in the southern islands as well but those areas were cleared by war time activities or development so little evidence of the plantations remain. Between the years of 1917 and 1944, large swaths of land were converted to sugarcane (*Saccharum* spp.) on the southern islands of Rota, Aguiguan, Tinian and Saipan during the Japanese colonization of those islands (Spoehr, 1957).

Changes in forest distribution and composition continued during the considerable destruction that occurred during World War II. During this time, Guam, Rota, Tinian, and Saipan were heavily bombed prior to the landing of Allied forces in 1944. Following the initial bombings and weeks-long battles in the Marianas, the U.S. military quickly began to develop the islands to maximize their strategic potential. Extensive military infrastructure was constructed on Guam, Tinian, and Saipan. Although the full extent of habitat loss during WWII is difficult to determine, photos from the time period show extensive alteration to the landscape and native forests in general. For example, based upon some reports, between only 3% and 5% of Tinian's forest was estimated to remain on the island following the conclusion of wartime activities (Engbring et al., 1986).

Invasive Species

Invasive species have had tremendous impacts upon the habitats in the Marianas. [Table 3](#) lists the key invasive species known to be established in the Marianas that impact forests.

Forest degradation by invasive animals

Following the end of WWII, the widespread introductions of nonnative plants and animals accelerated with the advent of new and additional human activity and commerce. The brown tree snake (*Boiga irregularis*) (BTS) ([Savidge, 1987](#)) was inadvertently introduced to Guam following WWII and has caused the extirpation or extinction of forest birds on Guam ([Savidge, 1987](#)). The loss of the birds has caused significant effects within the forest, most notably the loss of a major seed dispersers ([Egerer et al., 2018](#)). Seeds from native trees that depend upon the birds for dispersal are no longer being moved. Therefore, seeds fall directly from the parent tree and sprout beneath, but the high density of seedlings causes almost complete mortality ([Rogers et al., 2017](#); [Egerer et al., 2018](#)).

Native forests have also been severely degraded by the introduction of ungulates including cattle, deer, goats, and pigs on the islands of Guam, Rota, Aguiguan, Tinian, Saipan and several of the northern islands ([Liske-Clark, 2015](#)). On all of these islands, populations of feral ungulates browse the forest understory impeding recruitment and leading to increased erosion ([Kessler, 2011](#)). Aerial photos from before and after the introduction of pigs and goats on Sarigan and Anatahan illustrate the tremendous impacts of the browsing to forests ([Kessler, 2011](#)). Pigs were already established on Anatahan during the late 1890s ([Fritz, 1902](#)) and goats are thought to have been introduced in about 1960 ([Reichel, 1988](#)). From 1890 until 2002, approximately 2153 ha of forest was converted to swordgrass or bare ground by browsing ungulates on the island of Anatahan ([CNMI, DFW, 2000](#)). On Guam, invasive pigs and deer are known to have species-specific negative effects on seedling dispersal and recruitment. On Rota, deer in particular, are responsible for high seedling mortality rates thereby playing a major role in forest species structure and composition ([Gawel et al., 2018](#)).

Forest degradation by invasive insects

Coconut Rhinoceros Beetles (CRB) primarily impact coconut palms by boring into the crowns or tops of the tree damaging growing tissue and feeding on tree sap, potentially destroying the trees ([CNAS, 2016](#)). The CRB also feeds on a variety of other plant species including other palms, banana, pineapple, and sugarcane. Coconut trees have been heavily decimated on Guam where the CRB was first detected in 2005 and has since been found in Rota ([CNAS, 2016](#)). The loss of coconut palms may have direct negative consequences such as overall loss of forest cover.

The nonnative cycad aulacaspis scale (*Aulacaspis yasumatsui*) quickly causes mortality of all life stages of *Cycas micronesica* or fadang, an endemic species that was once dominant in the native limestone forests on Guam ([USFWS, 2015a](#)). It was introduced to Guam in 2003, possibly via importation of the landscape cycad, *Cycas revoluta* ([Marler and Lawrence, 2012](#)). In 2002, prior to the scale infestation, *C. micronesica* was the most abundant tree species on Guam ([Donnegan et al., 2002](#)). By 2005, the cycad aulacaspis

Table 3 Invasive species of concern in Mariana Islands forests.

Common name	Scientific name	Primary species affected	Impacts to forest	Island impacted
Coconut rhinoceros beetle (CRB)	<i>Oryctes thinoerosrhin overos</i>	Coconut palms	Loss of forest and brush cover and edible flowers (i.e., fruit bat)	Guam
Cycad aulacaspis scale	<i>Aulacaspis yasumatsui</i>	Cycads	Loss of dominant native forest component	Rota
Vines (Ivy Gourd, Bitter Melon, Mile-a-Minute, Mikania, Woodrose, Chain of Love)	<i>Coccinia grandis</i> , <i>Momordica charantia</i> , <i>Mikania scandens</i> , <i>Mikania micrantha</i> , <i>Merremia tuberosa</i> , <i>Antigonon leptopus</i>	Native vegetation	Highly degraded forest by outcompeting other plants for resources such as water and sunlight. If left unchecked vines can smother full grown trees and prevent recruitment	Guam
Feral ungulates (goats and pigs, deer)	(<i>Capra hircus</i> , <i>Sus scrofa</i> , <i>Rusa marianna</i>)	All forest types	Dig up soils, facilitating erosion, compete with native species for resources, consume or otherwise destroy natural resources, spread pest species through moving seeds, soil compaction	Rota
Rodents (black rats)	<i>Rattus rattus</i>	Native vegetation, prey on native and non-native fauna, including birds	Prevents recruitment, damage to crops, compete with forest birds for seeds/fruit	Guam
Brown tree snake	<i>Boiga irregularis</i>	Prey on birds, reptiles	Without birds, the vegetation has reduced dispersal ability and germination success	Guam
Other non-native plants Lantana, Fountain grass, tangantangan, Bidens, Koster's curse, and Wedelia	<i>Lantana camara</i> , <i>Cenchrus setaceus</i> , <i>Leucaena leucocephala</i> , <i>Bidens alba</i> , <i>Clidemia hirta</i> , <i>Sphagneticola trilobata</i>	Native vegetation	Competition with native vegetation for space, light, water, and other resources	Guam

scale had spread throughout the forests of Guam causing more than 90% mortality in once healthy populations in certain areas (Marler and Lawrence, 2012). To date, release of biocontrols to abate the scale infestation have been unsuccessful (USFWS, 2015a). In addition, three other insects a nonnative butterfly (*Chilades pandava*), a nonnative leaf miner (*Erechthias* sp.), and a native stem borer (*Dihammus marianarum*), opportunistically feed on *C. micronesica* weakened by the cycad aulacaspis scale, compounding its negative impacts (Marler, 2013). The significant ongoing loss of this once dominant component could result in a negative cascading effect for native limestone forests (Marler and Lawrence, 2012).

Forest alteration by invasive plants

The negative impacts of nonnative plants on forests are seen throughout a majority of the Marianas. The impacts include the alteration of the wildfire regime and the creation of large swaths of monotypic stands of nonnative species that outcompete and crowd out native forest plant species. Historically and presently, the most likely source of introduction of nonnative plant species is inadvertent or intentional transport of soil, seeds, or plants intended for ornamental or farm use, often without knowledge of their deleterious effects (Space and Falanruw, 1999).

Over 100 plant taxa have been introduced to the Marianas, and at least one-third of these have become pests (i.e., injurious plants) (Stone, 1970; Mueller-Dombois and Fosberg, 1998). Of these approximately 30 nonnative pest plant species, at least nine species are known to be habitat-altering, including trees such as lantana (*Lantana camara*), grasses such as fountain grass (*Cenchrus* (= *Pennisetum*) *setaceus*), and tangantangan (*Leucaena leucocephala*) (Space et al., 2000).

The greatest risk posed by nonnative plant species in the Marianas is aggressive displacement of native species. One of the most invasive plants in the Marianas is lantana, a branched shrub up to 10 ft. (3 m) tall, first brought to the Marianas as an ornamental plant and first reported as naturalized on Tinian in 1930 (Space and Falanruw, 1999). Lantana is aggressive, thorny, and forms thickets, crowding out and preventing the establishment of native plants (Davis et al., 1992; Wagner et al., 1999). Recognized as a serious pest species in Micronesia by the 1940s (Denton et al., 1991), lantana was reported as abundant and widespread on the islands of Tinian and Aguiuan in the 1990s (Denton et al., 1991; Space and Falanruw, 1999). Ungulates can exacerbate the spread of lantana and other nonnative plants as has occurred on the island of Aguiuan, where goats facilitate lantana's spread by eating nearly everything else with the exception of lantana (Thaman, 1974; Denton et al., 1991).

Another nonnative plant species of concern is tangantangan, widely considered invasive in many parts of the world. Native to the neotropics, tangantangan is a nitrogen-fixing shrub and an aggressive competitor that often forms the dominant element of the vegetation (Geesink et al., 1999). It alters the chemistry of soils to its own benefit and this competitive advantage has allowed it to now cover approximately 29% of Tinian (Marler et al., 2016).

Additional invasive plant species are located on Rota, Tinian, Saipan, and Guam including ivy or scarlet gourd (*Coccinia grandis*), molasses grass (*Melinis minutiflora*), and fountain grass (*Pennisetum setaceum*) (Space et al., 2000), all of which often cause harm to forests where they are introduced through military or civilian activities. In 2004, more than one third of all trees in Saipan, Tinian, and Rota were affected by invasive vines which can grow into dense patches that smother and kill host trees by blocking out sunlight (Liske-Clark, 2015). Invasive vines also reduce light availability under the canopy, impacting understory plant species composition and the rate of forest regeneration. Furthermore, many nonnative species including lantana, molasses grass, and fountain grass alter fire ecology (Space and Falanruw, 1999) with detrimental effects on forests.

Forest Loss From Volcanic Activity

As noted previously, volcanism has historically caused periodic destruction of forests of the northern islands. For example, Anatahan's eruption in 2003 and Pagan's eruption in 1981 caused major alterations to the island's forests (Kessler, 2011). In particular, the large amount of ash and cinder produced by these events completely wiped out large sections of forest which are just now recovering by colonization from early successional species. At the north end of the archipelago, the island of Uracas still lacks native forest (or forest of any kind) due to being one of the most active volcanoes of the western Pacific. Additionally, the islands of Asuncion, Agrigan, and Guguan have all experienced eruptions since 1900 resulting in significant forest loss (Tanakadate, 1940).

Development

Development is a major factor impacting forests throughout the Mariana Islands. Since humans first arrived in the islands, forests and other land cover types have been cleared and modified for human activities. The U.S. military claimed nearly one-third of the lands on Guam after World War II and have modified large areas of former forest. Forest destruction continues with the military build-up, as roughly 862 ha of native and secondary forest are being converted into a Cantonment and a Live Fire Training Range (USFWS, 2017). As part of the rebalancing of military forces to the Asia Pacific region, the northern portion of Pagan Island and the northern two-thirds of Tinian Island are being considered for live fire ranges and training as part of the Commonwealth Joint Military Training (CJMT). The area leased by the military for CJMT is 6195 ha and contains roughly 4593 ha of forests (U.S. Navy 2017). Based on preliminary planning documents, the military does not intend to develop or clear the entirety of the area and large tracts of land will be preserved or even enhanced for wildlife usage. The CJMT build-up is still in its planning stage and areas of proposed development or clearing will likely change making it difficult to determine the amount of forests that will be impacted.

Commercial and residential development continues to have a significant impact on all land cover types in the southern inhabited islands. The direct clearing of land for both large and small scale projects often results in the permanent loss of forests. Guam is the most populated and developed of the islands. The increase in population from the military build-up will likely result in a corresponding increase in commercial and residential development which may impact forests. In the CNMI, there have been several periods of rapid development coinciding with increased tourism. Several large-scale resorts are proposed on both islands in areas that are primarily forested. On Rota, small scale development for homes or agriculture is common. The islands north of Saipan are either uninhabited or contain very small populations, however infrastructure in the northern islands has begun to allow for people to reside on Alamagan, Pagan, and Agrihan.

Typhoons

Typhoons and super typhoons have had major impacts on forests in the Marianas. Intense winds can defoliate trees, break primary branches, and uproot or topple trees. Forests can take several years to recover and during this time the habitat is susceptible to encroachment from invasive trees, shrubs, and vines (Marler, 2001). "Dry" typhoons have very little rainfall, causing salt water to be carried by the wind and deposited far inland. This causes the leaves on most dicot trees to wither and fall within 2 days of a storm and can cause mortality (Kerr, 2000). While some coastal land cover types are adapted to salt spray, native, secondary, monoculture, and *Leucaena* forests in the Marianas are heavily impacted. The salt spray kills large amounts of vegetation, which may not regenerate until rains have washed away the salt (Kerr, 2000). Most forest types typically recover and are refoliated within 1 year (Kerr, 2000), but the temporary change in canopy cover can allow for the encroachment of invasive plants.

Fire

Wildfire is very rare in the Marianas as most fires are typically caused by humans either intentionally for the clearing of land or unintentionally from improper disposal of lit cigarettes. In addition, some hunters on the southern inhabited islands start grassland fires to attract deer since deer forage on the new grass shoots following a fire, the exposure making them easier to hunt. The lack of rainfall during the dry season desiccates grasses, trees, and leaf litter providing additional fuel for fires. These fires, which are often set in the dry season, can spread and cause significant damage to adjacent forests converting these forests to bare ground and facilitating the colonization of invasive plants.

Climate Change

Climate change related stressors (i.e., increased precipitation, sea level rise, increased typhoon intensity and frequency) cause ongoing impacts to this and other land cover types. However, the magnitude of the impacts are not discrete events but occur continuously on a longer time scale. Therefore, we do not see climate change related stressors as the primary threat to the forests at this time.

Conservation Efforts

Impacts from stressors are addressed through various management approaches such as active (on-the-ground) management (i.e., predator and invasive species control, fencing, reintroduction, etc.), land protections, laws and regulations, and education and outreach. These approaches are implemented by numerous government agencies (federal, territorial, and commonwealth), private organizations, and non-governmental organizations (NGOs).

Federal

Endangered species act

The Endangered Species Act of 1973 (ESA) aims to provide a framework to conserve and protect endangered and threatened species and their habitats. As habitat loss is the primary threat to most imperiled species, the ESA allowed the U.S. Fish and Wildlife Service (USFWS) and National Marine Fisheries Service (NMFS) to designate specific areas as critical habitat zones. In 1978, Congress amended the law to make critical habitat designation a mandatory requirement for all threatened and endangered species.

Approximately 3355 ha has been designated as critical habitat on Guam and Rota for four species (Mariana crow, Mariana fruit bat, Guam Micronesian Kingfisher, and the Rota bridled white-eye) under the ESA. On Guam, 152 ha of critical habitat was designated for the Mariana crow, Micronesian kingfisher, and Mariana fruit bat and is comprised of 97 ha of native forest and 30 ha of monoculture forest. On Rota, approximately 3059 ha of native forest, 83 ha of secondary forest, 51 ha of monoculture forest, and 35 ha of *Leucaena* forest was designated for the Mariana crow and Rota bridled white-eye.

Sikes act and the integrated natural resources management plan

The Sikes Act (16 U.S.C. 670) was originally passed in 1960 to direct the United States Department of Defense (DoD) to carry out conservation and natural resource rehabilitation projects on military installations in coordination with local and federal fish and wildlife agencies. Installations are required to create an Integrated Natural Resources Management Plan (INRMP) which describes future and ongoing conservation projects on military lands. In the Mariana Islands, the DoD manages large tracts of lands on Guam, Tinian, and Farallon de Medinilla (FDM). Many of the projects proposed in the INRMP are required or recommended by other laws and regulations, including the Endangered Species Act and Clean Water Act. The U.S. military owns nearly 7689 ha of forests on Guam and roughly 4047 ha of forest on Tinian which are included in several conservation actions proposed in their INRMPs.

Table 4 below shows the forest types on DoD lands on Tinian and Guam.

Guam Micronesian kingfisher memorandum of agreement (MOA)

In 2015, the U.S. Fish and Wildlife Service (USFWS) entered into an agreement with the Department of the Navy (DON) on conservation efforts to protect habitat (which includes forest habitat) in northern Guam for the benefit of the Guam Micronesian kingfisher. For the kingfisher to be recovered in Guam, 4659 ha of habitat is needed, with 3309 ha of that on DoD lands. Through the Integrated Natural Resources Management Plan (INRMP) the DON plans to restore and manage 2118 ha to offset the loss of 540 ha of kingfisher habitat due to the planned military relocation from Okinawa to northern Guam (USFWS, 2015a,b). Projects include fencing in large areas of forest, removing ungulates, replanting native trees (including threatened and endangered species), and removing invasive plants.

Local Permitting

In Guam, Public Law 25–152 was put in place to control accelerated soil erosion and manage nonpoint source pollution. This regulation allows for the Guam Department of Agriculture (GDOA), Division of Aquatic and Wildlife Resources (DAWR) to review all development projects which will involve the clearing of forest (and other) habitat prior to the start of project activities to ensure there are no negative impacts to protected species or resources.

Table 4 Forest types on Department of Defense (DoD) lands on Guam and Tinian (Reeves and Amidon, 2018).

Forest subtype	Acres on Guam	Acres on Tinian
Native	11,735	183
Secondary	5203	4198
Monoculture	1208	5375
<i>Leucaena</i>	18,698	10,537

In the CNMI, the Northern Mariana Islands Administrative Code (NMIAC) Chapter 65-30, § 65-30-101 details the permit requirements for any land clearing activities. It states “No person shall commence or continue any earthmoving activity including grading, filling, or clearing of vegetation without a DEQ Earthmoving and Erosion Control Permit issued in accordance with the regulation.” In order for land clearing to commence, CNMI DFW, historic preservation, coastal resource management, and zoning must all approve the permit. It is the role of CNMI DFW to review all land clearing projects and determine whether locally or federally protected species or resources will be impacted. This mechanism was put in place to ensure no unauthorized clearing of forest (or other) land cover types occurs in the CNMI.

Protected Lands

There are several categories of protected lands in the Marianas including conservation areas, national parks, a national wildlife refuge, and the only mitigation bank in the Pacific islands. These lands were designated by federal or local governments for the conservation of natural resources and have protections regarding development, hunting, fishing, wildlife-oriented recreation, and other uses. Regulations vary among protected areas, as each area has a distinct history and purpose for protection (Liske-Clark, 2015).

There are conservation areas established on Guam, Rota, Tinian, and Saipan. These areas are set aside by the local government or the DoD to restrict the activities in an effort to minimize impacts to natural resources. In the CNMI, these lands are designated through the passage of a congressional bill and are under the ownership of the CNMI Department of Lands and Natural Resources. On Guam, lands are placed under the ownership of the Government of Guam or DoD.

Conservation lands comprise 22% of Rota, 4% of Tinian, and 9% of Saipan. Of the northern islands, the entire island of Sarigan is regulated by the Division of Fish and Wildlife and Guguan, Asuncion, Maug, and Uracas are designated wildlife conservation areas. No people are allowed on these islands without prior approval from the Director of the CNMI DFW, so human impact to forest lands is minimal. CNMI conservation lands total approximately 5560 ha, representing 12% of the total land area (Liske-Clark, 2015).

Approximately 10,182 ha of forest are classified as reserves or protected areas across the Mariana archipelago including 7263 ha of native forest, 2103 ha of secondary forest, 466 ha of monoculture forest, and 349 ha of *Leucaena* forest (Reeves and Amidon, 2018). Table 5 summarizes the protected areas in the Marianas (Figs. 10–13).

Invasive Species Management and Control

Biosecurity

A major biosecurity focus within the Mariana Islands is preventing the spread of BTS to the Northern Mariana Islands from Guam. In this effort, federal agencies support local capacity both in Guam and the CNMI. On Guam there are extensive efforts to keep BTS out of the transportation chain, effectively reducing the potential for BTS to be accidentally transported from the island (Brown Tree Snake Technical Working Group (BTSTWG), 2015). In the CNMI, efforts are undertaken to ensure that high risk cargo and craft arriving from Guam are inspected to reduce risks of BTS accidentally arriving and establishing. These efforts include inspection of all arriving cargo from Guam to the CNMI by BTS detection dogs as well as specialized trapping around all major ports of entry. Control and management activities in regards to the BTS are highly effective and since enacted, credible BTS encounters outside of Guam and its native range have been reduced and at present there are no known populations established outside of its native range and Guam (Brown Tree Snake Technical Working Group (BTSTWG), 2015). Nevertheless, biosecurity mechanisms rarely eliminate the risk and the situation with the BTS on Guam needs to be continually monitored, enforced and adjusted as needed to best ensure that BTS do not accidentally become established in the CNMI or elsewhere.

The University of Guam and the College of the Northern Mariana Islands provide research and extension services which in part support invasive species management. Activities include CRB monitoring and management and research programs (Brown Tree Snake Technical Working Group (BTSTWG), 2015). Similarly, both the CNMI and Guam governments have staff which support management of various established pest species and provide natural resource management, conservation and restoration efforts. The DoD on military lands also has active natural resource programs including BTS management, feral ungulate control, habitat restoration and fencing (Brown Tree Snake Technical Working Group (BTSTWG), 2015).

These efforts to reduce the presence or impact of invasive species offer the potential to protect both the quality and quantity of vegetation within any habitat, including forests, as well as species that depend on the vegetation.

Partnerships

Micronesia Challenge

In 2006 the Republic of Palau, the Federated States of Micronesia, the Republic of the Marshall Islands, the U.S. Territory of Guam, and the U.S. Commonwealth of the Northern Mariana Islands committed to conserve at least 30% of the near-shore marine resources and 20% of the terrestrial resources across Micronesia by 2020. This pledge has become known as the Micronesia Challenge. The Challenge aims to preserve these resources for the benefit of future generations, to sustain livelihoods, and to sustain each island's unique biodiversity (Micronesia Challenge, 2012).

Table 5 Conservation areas of the Marianas (Berger et al., 2005; Guam Division of Aquatic and Wildlife Resources (DAWR), 2006; SWCA Environmental Consultants, 2010a,b; U.S. Fish and Wildlife Service (USFWS), 2007; Cogan et al., 2013; Reeves and Amidon, 2018).

<i>Conservation area (forest subtypes)</i>	<i>Location</i>	<i>Purpose</i>	<i>Enabling law or agreement</i>
Sabana heights wildlife conservation area (N S M L)	Rota, Sabana plateau	Terrestrial, for wildlife conservation	Rota Local Law 9-1 and regulations promulgated under Public Law 2-51
I Chenchon Park Wildlife Conservation Area and Bird Sanctuary (N S M)	Rota, cliffs along eastern coast	Terrestrial, for wildlife conservation and especially for sea birds	Rota Local Law 9-1 and regulations promulgated under Public Law 2-51
Wedding Cake Mountain Wildlife Conservation Area (N S M L)	Rota, Taipingot Peninsula on southwest end of island	Terrestrial, for protection of all wildlife, plants, and soils	Rota Local Law 9-3 and regulations promulgated under Public Law 2-51
Saipan Upland Mitigation Bank (N S L)	Saipan, upland areas of Marpi region on north end of island, encompassing the Marpi Commonwealth Forest	Terrestrial, to provide “credits” for sale to developers as a mitigation measure for the take of Nightingale Reed Warblers; and for preservation of wildlife	CNMI Public Law 10-84; Saipan Upland Mitigation Bank Agreement between CNMI and USFWS; and regulations promulgated under Public Law 2-51
Bird Island Wildlife Preserve (N S L)	Saipan, lands on Saipan island to the west of Bird Island	Terrestrial, for preservation of wildlife	CNMI Public Law 10-84
Bird Island Sanctuary (N S L)	Saipan, lands and waters surrounding and including Bird Island (N L)	Terrestrial and marine, no-take zone for all natural resources; natural laboratory for educational purposes	CNMI Public Law 12-46
Kagman Wildlife Conservation Area (N S M L)	Saipan, lands on eastern side of Kagman Peninsula	Terrestrial, for preservation of wildlife	CNMI Public Law 10-84
American Memorial Park National Park (N S M L)	Saipan	To commemorate those who lost their lives on the Mariana Islands in military campaigns during World War II. Protects several historical and cultural sites and provides recreational areas for the public	P.L. 95-348 (1978)
CNMI Mitigation Area (N S M L)	Tinian, north of airport	Compensate for loss of Tinian monarch habitat as a result of airport expansion	Biological Opinion (1-2-98-F-06) for the Federal Aviation Administration
Asuncion Island (N M)	Asuncion Island	Terrestrial, to be maintained as an uninhabited place and used only for the preservation and protection of natural resources, including but not limited to bird, wildlife and plant species	CNMI Constitution, Article XIV, Section 2 and CNMI Public Law 14-49
Guguan Island (N)	Guguan Island	Terrestrial, to be maintained as an uninhabited place and used only for the preservation and protection of natural resources, including but not limited to bird, wildlife and plant species	CNMI Constitution, Article XIV, Section 2 and CNMI Public Law 14-49
Maug Island (N M)	Maug Island	Terrestrial, to be maintained as an uninhabited place and used only for the preservation and protection of natural resources, including but not limited to bird, wildlife and plant species	CNMI Constitution, Article XIV, Section 2 and CNMI Public Law 14-49
Uracas Island (None)	Uracas Island	Terrestrial, to be maintained as an uninhabited place and used only for the preservation and protection of natural resources, including but not limited to bird, wildlife and plant species	CNMI Constitution, Article XIV, Section 2 and CNMI Public Law 14-49
Anao Conservation Area (N M)	Northeastern Guam	Wildlife, species conservation, outdoor recreation	Guam PL 16-62
Bolanos Conservation Area (N M)	Southern Guam	Hunting, outdoor recreation, species conservation	Guam PL 16-62
Cotal Conservation Area (S M)	Southern Guam	Species conservation	Guam PL 16-62

Haputo Ecological Reserve Area (N M)	Northwestern Guam	Preserving examples of ecosystems and genetic diversity while providing opportunities for scientific research. Mitigation for construction of Kilo Wharf, Outer Apra Harbor; part of Guam NWR Overlay	Chapter 15, OPNAVINST 5090.1; Chapter 17 of the NAVFAC P-73 Real Estate Manual; 36 CFR 251.23; 40 FR 38; and HR 5602, The National Heritage Policy Act of 1979 (March 15, 1984)
Orote Ecological Reserve Area (N S L)	Southern coast of Orote Peninsula, western Guam	Same as Haputo Ecological Reserve Area	Same as Haputo Ecological Reserve Area
War in the Pacific National Park (N S L)	Guam, 7 units Asan Beach, Asan Inland, Agat, Piti, Mt Alifan, Mt. Tenjo/Mt. Chachao, Fonte Plateau	To commemorate the bravery and sacrifice of those participating in the campaigns of the Pacific theater of World War II and Conserve and interpret outstanding scenic and historic values and objects for the benefit of present and future generations	Public Law 95-348, 92 Stat. 492, 16 USC 460dd (1978)

Interactions of All the Above

The primary stressors to forests include habitat loss and destruction caused by development and the introduction of invasive plants and animals. These stressors are significant and ongoing, act in concert with other stressors, and are expected to continue or increase in magnitude and intensity into the future without effective management actions to control or eradicate them.

Current conservation efforts taken by Federal, State, private, and agency partnerships combined with laws and regulations limit some of the effects of the stressors on forests, but do not eliminate them. Without active management, forests will continue to be degraded and destroyed. Increased levels of restoration and conservation efforts such as invasive species management, restoration of lands to native dominated forests and a reduction in the level of development have the potential to limit the degradation or loss of forests or even reverse any ongoing degradation occurring for these forest subtypes.

In summary, all forest sub-types across the Marianas are moderately resilient, aside from *Leucaena* forests which are highly resilient. Their rapid growth, and possibly allelochemical attributes allows it to form dense thickets that crowd out other vegetation making it highly resilient (Little and Skolmen, 1989). Development and invasive species have negatively impacted the quantity and quality of native forests and to some degree secondary forests. Development has reduced the quantity of native forests primarily on the southern islands. However, all forest types remain distributed across several islands throughout the Marianas (moderate redundancy). The current stressors or conservation actions do not seem to have significantly reduced the species richness or genetic variation, therefore representation remains moderate (Table 6).

Future Scenarios

The condition of Mariana Islands Forests in the foreseeable future is based on potential changes in three conservation management parameters (CMPs). These conservation parameters capture the social and legal mechanisms under which natural resource conservation is carried out. The CMPs are as follows:

Fig. 10 Native forest reserve type summary (Reeves and Amidon, 2018).

1. *Conservation Values*: stakeholder involvement and public opinion determine the formulation, implementation, and funding of natural resource conservation within laws and development plans.
2. *Laws and Biosecurity*: national, state, county, and city laws and regulations are the means by which natural resource conservation and biosecurity are supported and implemented (e.g., hunting regulations, Clean Water Act, Endangered Species Act, and local laws, etc.).
3. *Development or Conservation Planning*: national, state, county, city, and private development plans or conservation plans define specific actions that result in losses or gains in natural resource conservation and biosecurity (impacts are only realized at the time of implementation).

These conservation management parameters are critical factors that drive the direction and magnitude of natural resource conservation, and determine foreseeable future scenarios. The year 2035 is the extent of the “foreseeable future,” and is based on the projected divergence of IPCC Representative Concentration Pathway (RCP) climate change scenarios (van Vuuren et al., 2011; Miller, 2018).

The four foreseeable future scenarios considered in this assessment are:

Future Scenario One, Status Quo—the most likely foreseeable future; no change in natural resource conservation in the CMPs, so the current rate of change in land cover continues through the foreseeable future.

Future Scenario Two—a slight increase in natural resource conservation in the CMPs marginally improves conservation management.

Future Scenario Three—a slight to moderate decrease in conservation actions in the CMPs substantially decreases conservation management.

Future Scenario Four—a moderate to large increase in conservation actions in the CMPs substantially improves conservation management.

The future condition of Marianas Forests in Scenario One, the status quo, was characterized from an assessment of change over time in Forest land cover obtained from existing land cover maps (Reeves and Amidon, 2018). Based on these land cover maps, an annual rate of change for each forest subtype was estimated, and a projected change (in acres/ha) was calculated for the year 2035 (Amidon and Reeves, 2018). The resulting information on changes in land cover by 2035, as derived from existing land cover

Fig. 11 Secondary forest reserve type summary (Reeves and Amidon, 2018).

change estimates, is the extent of Marianas Forest ecotypes that is expected in the foreseeable future under Scenario One, the status quo, where conservation efforts remain unchanged and the current rate of change in land cover is also unchanged.

The future conditions of Marianas Forests for Scenarios Two, Three, and Four cannot be quantitatively (acres/ha) estimated. However, the Scenario One estimate can provide a “baseline” for a qualitative characterization of changes in the future condition of Mariana Forests under Scenarios Two, Three, and Four.

Changes in human population are captured only by the changes in the “developed” land cover footprint derived from land cover map analysis (Amidon and Reeves, 2018). Impacts from other sources of human activities or human-caused stressors (e.g., plant and animal diseases, wildfires, invasive species, etc.) are not well characterized in the land cover changes, but significantly contribute to increases in the land cover area dominated by nonnative vegetation. For an assessment of island-by-island changes in human population, see Amidon (2018).

Also, note that island-wide implementation of the CMPs is unlikely to have a significant effect on climate-related stressors (temperature, precipitation, and severe weather) resulting from global warming by 2035. This lack of CMP climate effects is due to the global lag in climate response to changes in greenhouse gas emissions which occurs on the order of centuries rather than years (Solomon et al., 2009; Gillett et al., 2011; Jevrejeva et al., 2012). Evidence of climate effects is also confounded by the large annual variation in the Pacific islands climate parameters, which is much greater than projected climate change by 2035. Although impacts from climate-related stressors do not change across the four scenarios, they were included in this analysis because of their overall magnitude of potential importance to future ecotype viability.

Future Scenario One: Status Quo

Under Scenario One there is no change in the implementation of the three CMPs between 2018 and 2035. A continuing current rate of change in land cover through this foreseeable future results in a slow but continuous change in Mariana forest subtypes. The anticipated changes, under Scenario One, of each stressor important to the four Mariana forest subtypes are given in Table 7. The summary of the change in quality and quantity of the four Mariana forest subtype under Scenario One can be found in Table 8.

Under Scenario One, an expanding human population and increased development and general land use on all inhabited islands is anticipated (Amidon, 2018; Amidon and Reeves, 2018), and therefore Mariana forest stressors are expected to increase at a small

Fig. 12 Monoculture forest reserve type summary (Reeves and Amidon, 2018).

annual rate. Exceptions are a small to moderate annual rate of increase for development, wild fires, and surface air temperature, and a small annual rate of decrease for precipitation. On average, the percentage of land developed for residential, commercial, and agricultural purposes on the inhabited islands is expected to increase by 25% from 2016 to 2035. This rate is only true for the southern inhabited islands of Guam, Rota, Tinian, and Saipan. Data on rates of development for the remaining islands does not exist at this time. Based on the rate of development and land cover data, estimates of the amount and percent change in each forest sub-type from 2016 to 2035 on the southern inhabited islands of Guam, Rota, Tinian under Scenario One were calculated.

Overall, the continued gradual decline of all forest subtypes in the Marianas is predicted under Scenario One. Most development (agricultural, commercial, military, or residential) occurs within forests, resulting in ongoing forest loss and fragmentation reducing resilience and redundancy of all forest types. No change in native forest is expected on Guam (<1%) and a moderate decrease is expected on Rota (28%) as areas identified as homestead sites continue to be cleared. Secondary forest is projected to remain stable on Guam (1% decrease) and Rota (2% increase), and decline on Tinian (26%) and Saipan (40%) as forests are converted to scrub/grass and developed land cover types. Monoculture forest is projected to remain stable in the foreseeable future on these islands. *Leucaena* forest is projected to increase slightly on Guam (5%) and decline modestly on Tinian (9%) likely tied to increases scrub/grass and developed land cover types.

Future Scenario Two: There Is a Slight Increase in the CMPs That Marginally Improves Conservation Management

Under Scenario Two, conservation agencies and stakeholders work with increased but limited resources to slow or stop the degradation of landscape areas. Scenario Two is essentially 'status quo' with minor improvements in the three CMPs. This scenario is expected to have the second highest likelihood of occurring into the foreseeable future, being slightly less likely than Scenario One. The anticipated changes, under Scenario Two, of each stressor important to the four Mariana forest subtypes are given in Table 7. The summary of the change in quality and quantity of the four Mariana forest subtypes under Scenario Two can be found in Table 8.

Though there is an expanding human population in Scenario Two, development is not expected to substantially increase. A slightly improved biosecurity effort should help reduce invasive species and plant diseases but increases are still expected. The small

Fig. 13 Leucaena forest reserve type summary (Reeves and Amidon, 2018).

Table 6 Assessment of native forest resiliency, redundancy, and representation of forests in the Mariana Islands in their current condition.

Forest sub-type	Resiliency	Redundancy	Representation
Native forest	Slightly reduced but still moderate	Slightly reduced but still moderate	Slightly reduced but still moderate
Secondary forest	Moderate	Moderate	Moderate
Monoculture forest	Moderate	Moderate	Moderate
Tangantangan forest	High	Moderate	Moderate

increased support of natural resource management in the CMPs is not expected to greatly alter wildfire frequency and intensity, but these might (lower slightly) compared to Scenario One. The CMP supported conservation will not prevent, mitigate, or reverse the impacts of climate change-related stressors.

Under this scenario the decline of native and secondary/mixed forest subtypes in the Marianas is predicted to decrease or halt. Whereas, development (residential, commercial, or agricultural) in the past and present occurred largely within native forest, a slight increase in planning could target development to areas of past development or disturbance. Disturbed open fields or abandoned buildings could be developed to accommodate an increase in population allowing for tracts of all forest types to remain undeveloped and possibly move through successional stages towards native or secondary forest on the islands with functional seed dispersal systems.

Future Scenario Three: There Is a Small to Moderate Decrease in Conservation Actions in the CMPs That Substantially Decreases Conservation Management

Under Scenario Three, all natural resource management actions in the CMPs are set aside in deference to land use for economic development. With extensive localized management, some native species may persist in park-like settings or in areas where land development is not possible. The anticipated changes, under Scenario Three, of each stressor important to the four Mariana forest subtypes are given in Table 7. The summary of the change in quality and quantity of the four Mariana forest subtypes under Scenario Three can be found in Table 8.

Table 7 Responses of Mariana Forest stressors in foreseeable future scenarios.

Conservation management parameters (CMPs)				
Conservation values	Stakeholder involvement and public opinion influence the formulation, implementation, and funding of natural resource conservation and biosecurity (NRC/B) within laws and development or conservation plans			
Laws and biosecurity	National, state, county, and city laws and regulations are the means by which NRC/B are supported and implemented			
Planning for development or conservation	National, state, county, city, and private development plans or conservation plans define actions that result in losses or gains in NRC/B (impacts realized at implementation)			
Foreseeable Future Scenarios	and the resulting Mariana Forest conditions			
Use Foreseeable Future Scenario One as a “baseline” to characterize changes in <i>Conservation Actions</i> and <i>Forest Conditions</i> in Future Scenarios Two, Three, and Four	<i>Scenario One:</i> CMPs: unchanged in support for NRC/B <i>Conservation Actions:</i> no change; current rate of land cover change continues through the foreseeable future <i>Forest Condition:</i> area, quality, and sustainability slowly decrease through the foreseeable future	<i>Scenario Two:</i> CMPs: small increase in support for NRC/B <i>Conservation Actions:</i> marginal increase <i>Forest Condition:</i> area is unchanged through the foreseeable future; quality and sustainability are slightly enhanced through the foreseeable future	<i>Scenario Three:</i> CMPs: small to moderate decrease in support for NRC/B <i>Conservation Actions:</i> substantial decrease <i>Forest Condition:</i> urban and agricultural uses are prioritized over conservation; area, quality, and sustainability substantially decrease through the foreseeable future	<i>Scenario Four:</i> CMPs: moderate to large increase in support for NRC/B <i>Conservation Actions:</i> substantial increase <i>Forest Condition:</i> robust, sustained effort to restore, manage, and expand conservation; area, quality, and sustainability substantially increase through the foreseeable future
Stressors	Responses of Mariana Forest stressors			
Development	Small to moderate increase	No change (redevelop)	Moderate to large increase	Small to moderate decrease
Altered hydrology	No change to small increase	No change	Larger increase	Small decrease
Recreation/access	Small increase	Small increase	Larger increase	Larger increase
Invasive species	Small increase	Small increase	Larger increase	Small decrease
Plant diseases	Small increase	Small increase	Larger increase	No change to small decrease
Fire	Small to moderate increase	Small increase	Larger increase	No change to small decrease
Erosion	Small increase	No change	Larger increase	Small decrease
Climate:				
Temperature	Small to moderate increase	Small to moderate increase	Small to moderate increase	Small to moderate increase
Precipitation	Small decrease	Small decrease	Small decrease	Small decrease
Storms	Small increase	Small increase	Small increase	Small increase

Under this scenario the quality and quantity of all forest types in the Marianas is expected to rapidly decline. Development (residential, commercial, or agricultural) will increase substantially and continue to disproportionately impact Mariana forests relative to other land cover types. Overall, this will result in fragmentation and degradation of forests reducing resiliency, redundancy, and representation across all forest types.

Future Scenario Four: There Is a Moderate to Large Increase in Conservation Actions in the CMPs That Substantially Improves Conservation Management

Under Scenario Four, an overt and robust, active, ongoing effort is made to engage partners and stakeholders in identifying and prioritizing landscape areas needed for the conservation of native ecosystems, and to actively restore and expand these areas. A substantial emphasis on natural resource conservation is present in the three CMPs, reflecting increased societal concern for declines in natural habitats and biodiversity. Active and well-supported natural resource management begins to restore these habitats and ecosystems and expand their landscape areas. The anticipated changes, under Scenario Four, of each stressor important to the four Mariana forest subtypes are given in [Table 7](#). The summary of the change in quality and quantity of the four Mariana forest subtypes under Scenario Four can be found in [Table 8](#).

Under this scenario the rate of decline of all forest types in the CNMI is expected to halt allowing forests to regenerate and expand. The BTS will continue to hinder the natural regeneration of forests lost due to the absence of seed dispersers, but active restoration efforts by DOD and conservation agencies will aid in the creation of native forest habitat. Whereas, development (residential, commercial, or agricultural) in the past and present occurred largely within forest habitat, with a robust increase in

Table 8 (A–D). Estimated acreages and percent of island in each forest sub-type currently (2016) and in the foreseeable future (2035) for the islands of Guam, Rota, Tinian, and Saipan.

Island	Current (2016)		Future (2035)		% Change 2016 to 2035
	Acres	% of Land	Acres	% of Land	
Native forest ^a					
Guam	21,668	16%	21,681	16%	< 1%
Rota	10,052	47%	7,207	34%	– 28%
Tinian	1067	4%	471	2%	– 56%
Saipan	427	1%	637	2%	49%
Secondary forest ^b					
Guam	33,270	25%	32,946	25%	– 1%
Rota	2163	10%	2212	10%	2%
Tinian	6202	25%	4594	18%	– 26%
Saipan	10,656	36%	6369	22%	– 40%
Monoculture forest ^c					
Guam	1709	1%	1701	1%	0%
Rota	667	3%	772	4%	16%
Tinian	888	4%	1676	7%	89%
Saipan	526	2%	741	3%	41%
Leucaena forest ^d					
Guam	4914	4%	5137	4%	5%
Rota	229	1%	34	0%	– 85%
Tinian	8279	33%	7567	30%	– 9%
Saipan	5492	19%	5709	19%	4%

Percent (%) change is the difference between the % of land in 2035 and 2016. No data is currently available for projecting habitat change in the foreseeable future for the remaining islands in the archipelago (Amidon and Reeves, 2018).

^aNo change in Native Forest is expected on Guam, a moderate decrease is expected on Rota, a large decrease is expected on Tinian, and a large increase is expected on Saipan. The increase on Saipan is likely due to inconsistencies in classification. Native forest on Saipan is highly fragmented and has not been mapped well over the various assessments. Therefore, we consider that increases in native forest on Saipan are unlikely. The decline on Tinian is also likely to be due, in part, to classification inconsistencies. However, some decreases may occur on Tinian. Declines in native forest are expected on Rota as areas identified for homestead sites continued to be cleared.

^bSecondary forest is projected to remain stable on Guam and Rota and decline on Tinian and Saipan. A decline on Saipan is expected as a large proportion of the island is secondary forest and the increases in developed land cover is likely associated with losses in this forest sub-type. A decline on Tinian is also expected as approximately a quarter of the island is in this forest sub-type and increases in scrub/herbaceous and developed habitats are likely related to the loss of this forest sub-type.

^cBased on the analysis, monoculture forest is projected to remain stable on Guam and increase on the remaining islands. However, the increases on Rota, Tinian, and Saipan in this habitat are likely related to mapping error and inconsistent classification as new plantings of monoculture forest are not regularly encountered on these islands. The changes on Saipan and Rota are relatively small and consistent with mapping error. The increase on Tinian is substantial. However, review of the imagery from 2005 and 2016 indicates that the increase in this forest sub-type is likely due to misclassification. The monoculture forest in the 2016 map was present in the 2005 imagery and was likely misclassified due to the lower resolution of the imagery. Therefore, we conclude that changes in monoculture forest are unlikely under the status quo scenario.

^dThe analysis indicates that *Leucaena* Forest is projected to remain stable on Saipan, increase slightly on Guam, and decrease on Rota and Tinian. The projected decline on Rota is likely related, in part, to mapping and classification errors. Review of the imagery from 2016 and 2005 indicate that the extent of this forest type was consistent between both images and that the decline may be related to over estimates in the 2005 maps. The decline on Tinian is expected as approximately 1/3rd of the island is classified as this habitat and increases in Developed and Scrub/Herbaceous land cover types (see associated sections in Amidon and Reeves, 2018) on this island are likely related to the loss of this forest sub-type.

planning, development in forest habitat will be virtually non-existent and almost entirely occur in areas of past development or disturbance. Disturbed open fields and impaired forests will then be actively targeted for reforestation and restoration resulting in an increase in the quality and quantity of forested habitat.

Conclusion

Prior to the arrival of humans in the Mariana archipelago, native forest was likely widespread, contained a high amount of diversity, and recovered quickly from storms; thereby exhibiting high levels of resiliency, redundancy, and representation. As a result of natural and anthropogenic disturbance since the arrival of humans, a significant proportion of native forest was converted to three additional forest sub-types: secondary, monoculture, and *Leucaena* forests resulting in the current condition of Mariana forests.

Currently, the primary stressors to Mariana forests include invasive species, development, volcanic eruptions, typhoons, and fire. These stressors are serious and ongoing, and are expected to continue or increase in magnitude and intensity into the future. Without changes in current laws or regulations, biosecurity will continue to be an issue and continuing the spread and introduction of invasive plants, animals, and insects and their impacts throughout the archipelago. In addition, the threat of introduction of the BTS to the CNMI is ongoing, and will also continue to prevent the recovery of seed dispersing avian species hindering native forest

restoration on Guam. And without active management to halt or reduce the impacts of development and invasive species, the quantity and quality of Mariana forests will continue to decline and result in reduced resiliency, redundancy and representation.

Native and secondary forests are biologically important as they support native species and provide the conditions needed for their survival. The majority of remaining native (90%) and secondary forests (99%) are found on five of the southern islands (Guam, Rota, Tinian, Saipan, Aguiguan) which underscores the importance of these areas for biodiversity conservation in the Mariana archipelago. However, these islands also support the highest concentration of the human population and military activities which presents a greater risk of forest degradation and destruction as result of the ongoing impacts of development and invasive species.

Though conservation efforts by Federal, Territorial, Commonwealth, and multiple agency partnerships have been beneficial in helping to conserve and protect some of the remaining forests in Marianas, without increased efforts to address biosecurity, development, and invasive species, a decrease in the viability of Mariana forests is expected. Because the remaining native and secondary forests and reserve areas occur across public, private, and Department of Defense lands (including the USFWS Overlay Refuge), conservation of these areas will require continued efforts by all stakeholders.

Finally, in the foreseeable future, Scenario One, has the highest likelihood of occurring in relative to the other scenarios. Under Scenario One there is no change in the implementation of the conservation management parameters (CMPs). Scenario Two is based on a slight increase in the implementation of the CMPs, which marginally improves conservation management. Thus Scenario Two is expected to have the second highest likelihood of occurring into the foreseeable future, being slightly less likely than Scenario One. Scenario Three is based on a slight to moderate decrease in conservation actions in the CMPs which substantially decreases conservation management. Because there is a decrease in the implementation of the CMPs, Scenario Three would severely degrade and fragment native and secondary forest subtypes and result in reduced resiliency, redundancy, and representation. In Scenario Four, the substantial improvements in restoration for native and secondary forest subtypes would result in increased resiliency, redundancy, and representation. However, Scenario Three and Four have the lowest likelihood of occurring in the foreseeable future.

Overall, the CMPs are critical factors that drive the direction and magnitude of natural resource conservation and determine the foreseeable future scenarios. Any increase in the implementation of the CMPs will result in the greatest conservation returns for native and secondary forests (Scenario's Two and Four). Conversely, any decrease in the implementation of the CMPs will result in the least conservation returns for native and secondary forests (Scenario's One and Three). Thus, realistic expectations of the implementation of the CMPs were considered when determining the likelihood of occurrence for each scenario in the foreseeable future.

Abstract

Much world attention has been given to engineering solutions to the increasing threats of water scarcity and pollution in regions where aquatic systems have been lost or degraded. However, government leaders and decision-makers must acknowledge that this crisis cannot be solved without giving equal attention to protection of the Earth's remaining pristine lakes, rivers, wetlands and peatlands. Canada's Boreal Forest region encompasses some of the world's largest intact freshwater ecosystems, contains the highest concentration of wetlands—which hold billions of tons of carbon—with countless pristine lakes and free-flowing rivers and streams. The aquatic systems of the region benefit the lives of billions of people across the world by stabilizing climate, supporting ocean health, enhancing food security, protecting wildlife and influencing the global economy. Protection of Canada's Boreal Forest region and its waterways and wetlands, along with limiting greenhouse gas emissions, should be among the top global conservation priorities.

Introduction to the Globally Significant Aquatic Features of the Boreal

While most of the world is focused on water scarcity and pollution, a few places on earth still retain pristine and abundant water resources maintained by large areas of intact forests and wetlands (Fig. 1; Keddy et al., 2009). Canada's Boreal Forest (Fig. 2) is one of these regions. Canada contains, by some estimates, more than 20% of the world's wetlands (Scott and Jones, 1995; Webster et al., 2015) and the largest amount of surface freshwater within a single country (Minns et al., 2008), most of it within the Boreal Forest region (Fig. 3). Also within Canada's Boreal Forest are North America's most significant undammed rivers (Figs. 4 and 5A, B; Dyne-sius and Nilsson, 1994), millions of lakes (Fig. 4 and 5C) including some of the world's largest (Minns et al., 2008), and the world's most extensive peatland systems (Abraham and Keddy, 2005; Tarnocai, 2009; Keddy et al., 2009). All of these are embedded within a matrix of forested habitat, still largely unfragmented by industrial development, representing the world's largest intact forest ecosystem maintained for millennia by Indigenous communities who still rely on Canada's Boreal Forest for food, health and livelihoods (Karst, 2010).

Canada's Boreal Forest and its wetlands and waterways have an integral influence on the planet's climate and marine productivity in ways that impact hundreds of millions of people across the world in relation to global warming, food security, and economics (Dai and Trenberth, 2002; Dai et al., 2009). The value that Canada's Boreal Forest provides to the world in total ecosystem services has been estimated at 700 billion dollars annually, with more than half of that attributable to services provided by wetlands including carbon storage, water filtration, and flood control (Anielski and Wilson, 2009). This is 14 times greater than the value of natural resources (mining, forestry, oil and gas, hydroelectric generation) extracted annually from the region. Industrial resource extraction is also expected to decrease the ability of Canada's Boreal Forest to provide ecosystem services to society.

The rivers (Fig. 4) that drain Canada's Boreal Forests' 5.8 km² (1.4 billion acres) are among the earth's most significant in providing freshwater flow and nutrients to northern marine systems including the Arctic Ocean, Bering Sea, and Hudson and James Bay (Stewart and Lockhart, 2005). This input is critical in the formation of sea ice that cools the atmosphere through the reflection of solar radiation (Loeng et al., 2005) and provides the substrate for much of the biodiversity of that unique marine ecosystem including marine algae, plankton, fish, seals, whales, and polar bears (Stewart and Lockhart, 2005). Flows from Canada's Boreal Forest rivers also are key drivers in the dynamics of large deep ocean currents that link cold northern Polar waters with warmer tropical waters and have a major influence on global weather and future climate change (Dai and Trenberth, 2002; Dai et al., 2009).

Fig. 1 Wetlands of all shapes and sizes make up much of the landscape within Canada's Boreal Forest region like these in (A) northern Ontario, (B) northern Quebec, and (C) the Northwest Territories. Photos by Jeff Wells.

Peatlands (Fig. 6) and the sediments of lakes and river deltas of Canada's Boreal Forest are one of the world's largest stores of carbon (Wells et al., 2010). Canadian peatlands store an estimated 147 billion tonnes of carbon (Tarnocai, 2009) while the sediments in the delta of the Mackenzie River contain 41 billion (Tarnocai et al., 2009). The 208 billion tonnes of carbon estimated to be stored overall within Canada's Boreal Forest represent the equivalent of 26 years worth of world carbon emissions from the burning of fossil fuels as measured in 2006 (Carlson et al., 2009, 2010).

Fig. 2 North America's Boreal Forest biome (in *green*) as delineated by Brandt (2009). Canada's portion of the biome extends from the Alaska-Yukon border east to Newfoundland and Labrador.

Fig. 3 Canada's Boreal Forest contains the highest concentration of surface freshwater in the world with millions of lakes and ponds.

Fig. 4 Canada's Boreal Forest hosts more free-flowing rivers than anywhere else in North America although mega-hydro projects have been developed on many river systems as well. Four of the world's largest lakes are found wholly or partly in Canada's Boreal Forest region.

Globally Significant Biodiversity in Canada's Boreal Forest

The biodiversity supported by the wetlands and waterways of Canada's Boreal Forest is nationally and globally significant (Wells et al., 2010). Its large and long undammed rivers have become the last refuges for many of the world's sea-run migratory fish including species that have been lost or reduced in vast portions of their former range. For example, half of the remaining healthy populations of North America's Atlantic salmon (*Salmo salar*) are found in rivers within Canada's Boreal Forest (Fig. 7) and some of the most significant populations of Pacific salmon species occur in Canada's Boreal Forest rivers including the Yukon and the Stikine (Scott and Crossman, 1973; Augerot and Foley, 2005; Wells et al., 2010). The low human population density and lack of overexploitation of many of Canada's Boreal Forest lakes and rivers has permitted freshwater ecosystems to retain many natural qualities lost throughout most of the world including very large and long-lived fish. The sportfishing world record largest lake trout (*Salvelinus namaycush*) was a 72-pound individual taken on Great Bear Lake and the world record largest brook trout (*Salvelinus fontinalis*), Arctic grayling (*Thymallus arcticus*), and round whitefish (*Prosopium cylindraceum*) are all from waters within Canada's Boreal Forest (International Game Fish Association, 2010).

The 1–3 billion birds that breed in Canada's Boreal Forest are highly dependent on its wetlands and waterways (Cheskey et al., 2011; Wells and Blancher, 2011; Slattery et al., 2011). Some of the world's largest concentrations of waterfowl and shorebirds nest and feed in Canada's Boreal Forest wetlands including RAMSAR designated sites like the Polar Bear Provincial Park in the Hudson Bay Lowlands, the Peace Athabasca Delta, and Yukon's Old Crow Flats (Cheskey et al., 2011; Wells et al., 2013). The intact nature and remoteness of Canada's Boreal Forest watersheds has also shielded the region from the large numbers of invasive plants and animals that are causing major ecosystem degradation in much of the world.

Fig. 5 Within Canada's Boreal Forest biome are major free-flowing rivers like the Mackenzie River (A) in the Northwest Territories and the George River (B) in Quebec and the world's fifth largest and perhaps most pristine lake, Great Bear Lake (C) in the Northwest Territories. Photos by Jeff Wells.

Fig. 6 Wetlands dominate within Canada's Boreal Forest including some of the largest peatland systems in the world, some of the largest inland deltas, and major lakeshore freshwater marshes along its many large lakes and marine marshes and estuaries as well.

Large-Scale Industrial Activity Is Increasing

Although Canada's Boreal Forest is globally significant in the conservation values it still retains, the region is becoming increasingly impacted by large-scale industrial activities (Kreutzweiser et al., 2013). Already the footprint of industrial activity within Canada's Boreal Forest encompasses 730,000 km² (180 million acres) including logging, road building, mining, oil and gas extraction, and hydropower (Wells et al., 2010). A third of Canada's Boreal Forest region has been allocated by provincial governments for logging (Fig. 8A and B) and approximately 10% was under mining claims in 2008. There are 7000 abandoned mines (Fig. 8C) within Canada's Boreal Forest with 3000 of these within 1 km of a waterway (Wells et al., 2010) and over 230,000 of the active and abandoned oil and gas wells in Canada's Boreal Forest are within 5 km of a waterway. Ten thousand new oil and gas wells were drilled annually from 1999 to 2009 (Wells et al., 2010). There are over 600 dams generating hydropower across Canada with the largest in Canada's Boreal Forest region (Lee et al., 2012). Impoundments behind dams are estimated to have inundated 52,000 km² (12.9 million acres) of wildlife habitat (Wells et al., 2010) and over 130,000 km (80,778 miles) of river have been affected by flow regulation from dams in Canada (McAllister, 2000). At least 20 new large hydropower projects are planned or proposed and hundreds more identified as potential projects across Canada (Lee et al., 2012). The rapidly increasing effects of climate change are already manifesting themselves across Canada's Boreal Forest ecosystems, especially in wetlands and waterways through the melting of permafrost and drying of wetlands in the western part of the region (Schindler, 2001; Schindler and Lee, 2010). Industrial activities lessen the adaptability of natural habitats to adapt to these climate change impacts, especially because much of the water in Canada's Boreal Forest systems is not recharged on an annual basis but is the result of years of accumulation in ice and snow (Schindler, 1998a,b).

Fig. 7 Atlantic Salmon (*Salmo salar*) populations are now endangered in the United States, largely as a result of dams prohibiting access to upstream spawning grounds and pollution. But healthy populations remain in the undammed, free-flowing, and pollution-free rivers within Canada's Boreal Forest (shown in green).

A Bold Conservation Vision

Modern conservation science principles now recommend much higher protected areas benchmarks are required in order to have a reasonably high probability of retaining a region's species diversity and ecosystem functions (Noss et al., 2012; International Boreal Conservation Science Panel, 2013; Locke, 2013; Wilson, 2016; Dinerstein et al., 2017; Watson et al., 2018). These principles have been applied to Canada's Boreal Forest region and a resulting vision articulated that calls for the establishment of a series of large, interconnected protected areas that encompasses at least half of the region's 5.8 million km² and with industrial natural resource extraction activities that occur outside of these protected areas carried out with leading edge responsible development practices to ensure the retention of biodiversity and ecosystem function (International Boreal Conservation Science Panel, 2013).

Fig. 8 Examples of some types of industrial activity in Canada's Boreal Forest include road-building and forestry (A and B), these from northern Ontario, and mining (C), this the now abandoned Pine Point mine south of Great Slave Lake in the Northwest Territories. Photos by Jeff Wells.

The Canadian Boreal Forest Conservation Framework describes this vision and was endorsed by the Boreal Leadership Council, a coalition that includes First Nations, leading industries from many sectors, and environmental organizations (Carlson et al., 2015).

World-Leading Stewardship of Aquatic Resources

Major progress has been made in some jurisdictions toward protecting and maintaining their northern aquatic resources as a result of public support for increased land conservation efforts, particularly led by Indigenous governments. The provinces of Ontario and Quebec have each committed to protecting half of their northern regions, an area in total of more than 858,000 km² (Carlson et al., 2015; Wells et al., 2015). Indigenous governments throughout Canada's Boreal Forest region have been especially efficient in implementing conservation initiatives (Indigenous Circle of Experts (ICE), 2018). In 2012, the Indigenous Inuit and Cree governments in partnership with the Government of Quebec, established Tursujuq National Park, a 26,000-km² pristine network of rivers and streams along the northern shores of Hudson Bay in northwestern Quebec that weave together a wetland fabric of marshes, peatlands, ponds, and lakes (Wells et al., 2013; Carlson et al., 2015). The park encompasses at least three river systems totaling more than 300 km in length with headwater to mouth protection. These culminate with some of Quebec's most unique lakes: Lacs des Loups Marins (Seal Lakes) and Quebec's second largest lake, Lacs à l'Eau-Claire (Clearwater Lake), which was formed by an ancient massive meteor strike. The waterways and wetlands further upstream are home to a remarkable number of water-dependent species. The most surprising is its resident race of freshwater harbor seals (*Phoca vitulina mellonae*). Apparently landlocked for thousands of years, these seals somehow find enough open water and food through the winter for survival (Wells et al., 2010).

In Manitoba and Ontario, four Indigenous governments (Bloodvein River First Nation, Little Grand Rapids First Nation, Pauingassi First Nation, and Poplar River First Nation) in partnership with both provincial governments, have protected 30,000 km² of primary forest within the Pimachiowin Aki World Heritage Site that includes virtually the entire lengths of four free-flowing rivers (Fig. 9) with a total length of over 1200 km and that discharge 6.9 million m³ of freshwater into Lake Winnipeg, the world's 10th largest lake (Davidson-Hunt et al., 2012; Wells et al., 2014) and one suffering from polluted waters flowing into the lake from agricultural landscapes to its south and west (Schindler and Vallentyne, 2008).

In Labrador, the Innu Nation worked with the provincial government to establish the Mealy Mountains National Park and the Eagle River Waterways Provincial Park, two adjoining protected areas totaling over 13,000 km² (Carlson et al., 2015) and including headwater to mouth protection for the 200 km Eagle River which supports one of the area's largest runs of anadromous Atlantic salmon.

In the Northwest Territories, indigenous government land-use planning together with federal government initiatives has led to the establishment of more than 425,000 km² (105 million acres) of protected areas and interim protected areas (Wells et al., 2015). This includes the 30,000 km² (7.4 million acre) Nahanni National Park Reserve and adjoining 4850 km² (1.2 million acre) Náát-s'ihch'oh National Park Reserve that includes over 25,000 km of rivers and streams, the Thaidene Nene Indigenous Protected Areas that encompasses 2847 km² of wetlands and nearly 14,000 km of rivers and streams and the Edézhíe Indigenous Protected Area that encompasses 370,000 ha of wetlands and nearly 10,000 km of streams and rivers.

In the Sahtu Settlement Area of the Northwest Territories, the 93,300 km² (23 million acre) Tsá Tué Biosphere Reserve was established in 2016. The area is the homeland of the Sahtuto'ine, the "Bear Lake People." It encompasses Great Bear Lake, the world's

Fig. 9 The 300 km Blood Vein River flows unimpeded from headwaters in western Ontario to the east shore of Lake Winnipeg in Manitoba within the Pimachiowin Aki World Heritage Site. Photo by Jeff Wells.

eighth largest lake and perhaps the world's most pristine large lake, and most of its watershed. Within the Tsá Tué Biosphere Reserve are 992,000 ha of wetlands, 49,000 km of streams and rivers, and over 139,000 lakes.

In the Yukon, the final land-use plan for the 67,431 km² (16 million acres) Peel River Watershed was approved in 2019, requiring 55,858 km² (13.8 million acres) of new protected areas. The Peel River watershed includes six major river tributaries—the Snake, Wind, Bonnet Plume, Hart, Ogilvie, and Blackstone rivers that flow north into the Mackenzie Delta. The protected areas within the plan encompass 179,000 ha of wetlands, 62,000 km of streams and rivers, and 18,000 lakes. The watershed includes the traditional territories of four Indigenous governments, the Na-Cho Nyk Dän, Tr'ondëk Hwëch'in, Vuntut Gwitchin, and Teetl'it Gwich'in, all of whom led the initiative to protect the watershed.

The Government of the Northwest Territories initiated a water stewardship strategy for the Mackenzie River watershed in 2009 that involves collaborative planning with Indigenous governments, community based water monitoring, and the negotiation of transboundary water agreements with three provinces (Alberta, British Columbia, and Saskatchewan) and one territory (Yukon) with which the Northwest Territories share the Mackenzie River watershed ([Government of the Northwest Territories, 2010](#); [Webster et al., 2015](#)).

More to be Done

Protecting and maintaining the water resources of Canada's Boreal Forest will clearly require more attention and effort than ever before. The pace and scale of protected area establishment within Canada's Boreal Forest will have to reach unprecedented levels in coming years, including headwater to mouth protection for the world's last, large unfragmented rivers and their entire watersheds ([Lertzman and MacKinnon, 2013](#)). Land-use planning that is ongoing across many jurisdictions within Canada's Boreal Forest will have to more explicitly consider and integrate water and aquatic conservation values including maintaining intact waterways ([Schindler and Lee, 2010](#)).

New incentives will be needed to maintain the vast stores of carbon in Canada's Boreal Forest peatlands, forests, and waterways so they do not contribute to global warming. Large waterways and wetlands within Canada's Boreal Forest, especially the Mackenzie River Basin, the Yukon River Basin, the Hudson Bay-James Bay Lowlands, Labrador, and the Great Lakes-St. Lawrence Basin must also be the focus of renewed attention by Indigenous, provincial federal, and international leaders to develop joint protection and management strategies that recognize the global uniqueness and influence of these ecosystems.

A Last Great Conservation Opportunity

As governments around the world strive to enact the U.N. Sustainable Development Goals, including Goal 6—"Ensure availability and sustainable management of water and sanitation for all"—many are understandably focused on the twin issues of water scarcity and pollution that already impact billions of people. But equal attention must be given to another of the targets embedded within Goal 6—protecting and maintaining the Earth's last, large remaining pristine waterways and wetlands. As the human industrial footprint expands and global warming escalates, protection of these intact watershed will be absolutely critical to ensure both safe and adequate water for all but also to maintain ecosystem services and biodiversity, a goal of another U.N. convention, the Convention on Biological Diversity (the so-called Aichi Treaty). Maintaining the wetland and waterways of Canada's Boreal Forest in pristine, unfragmented and fully functioning condition should be a world priority.

Abstract

This section of the *Encyclopedia of the World's Biomes* covers the grassland, shrubland and savanna biomes through the individual regional ecosystems by which these biomes are expressed across the globe. Grasslands, shrublands, and savannas occupy upwards to 40% of the terrestrial surface of the earth, excluding Greenland and Antarctica. They occur on every continent except Antarctica and are found across the temperate and tropical zones of the world, as well as in the Arctic. Grasslands are defined as terrestrial ecosystems dominated by herbaceous plants, mainly graminoids in the Poaceae family (grasses) and related families, and which lack a considerable cover of woody plants. Shrublands are vegetation communities dominated by shrubs or short statured trees generally less than 5 m tall, often in a single canopy layer. Additional definitions used to define and describe grasslands, shrublands, and savannas are discussed. This overview article provides a brief introduction to the grassland, shrubland and savanna biomes with a focus on their global patterns of diversity, general ecology, and relationships to climate, disturbance and geology. The paleoecological origins of grassland, shrubland and savanna biomes and the evolution of important physiologic traits in ecosystem defining taxa are also explored. A review of the major grassland, shrubland and savanna ecosystems of the globe not covered by the articles in this section of the *Encyclopedia*, as well as references for further investigation, are provided. The articles in this Grasslands and Shrublands section, written by an accomplished set of authors, cover major grassland, shrubland, savanna, and woodland ecosystems in North America, South America, Europe, Asia, Africa, Australia, Micronesia, and Polynesia.

Introduction

Grasslands, shrublands, and savannas occupy upwards to 40% of the terrestrial surface of the earth, excluding Greenland and Antarctica (White et al., 2000). They occur on every continent except Antarctica and are found across the temperate and tropical zones of the world, as well as in the Arctic. Grasslands and shrublands are highly diverse in their vegetation structure and floristic composition, and in many cases their biodiversity, owing in large part to their broad range of climatic zones, widespread global distributions, and often long and complex geologic and evolutionary histories. In a broad sense, grasslands and shrublands are identified by a moderate to dense vegetation cover (> 10%) and a lack of a continuous and/or multi-layered tall tree canopy (i.e., non-forest). However, many different definitions exist for grasslands, shrublands, savannas, and woodlands (White et al., 2000; Dixon et al., 2014; Török and Dengler, 2018).

In general, a grassland is a terrestrial ecosystem that is dominated by herbaceous plants, mainly graminoids in the Poaceae (grasses), Cyperaceae, Restionaceae, and related families, and which lacks trees or a considerable cover of woody plants (White et al., 2000; Gibson, 2009; Dengler et al., 2014). A shrubland is vegetation that is dominated by shrubs or short statured trees, generally < 5 m tall, often in a single canopy layer. Shrub cover may be very dense to fairly open with considerable grass cover, but with shrubs common and evenly distributed throughout (Dixon et al., 2014). As with grasslands, shrublands also lack considerable tall tree cover (< 10%). Grasslands and shrublands may occur as distinct from one another, the physiognomy of each characterizing vast ecoregions. However, grasslands and shrublands also co-occur in a variety of ways; intermixed in distinct grassland or shrubland patches, as grassy shrublands, or grasslands with a sparse cover of shrubs.

Definitions for savanna vary considerably, as they exist along a continuum between forest and woodland on one side of the spectrum and treeless grasslands on the other. Definitions also differ for savannas of temperate versus tropical regions. In general a savanna is defined as vegetation comprised of continuous grass cover with scattered trees, with some definitions including vegetation with shrub understories. Savannas are visually recognizable by their simple two layered structure: a single layer of scattered trees over top a continuous low statured understory layer of grasses or shrubs (Dixon et al., 2014). Tree cover thresholds can range from 10% to 60% (and as high as 75%) among savanna definitions in the literature (Dixon et al., 2014; Faber-Langendoen et al., 2016), although these upper limits exceed tree cover thresholds used to define woodlands. Faber-Langendoen et al. (2016) settle on

a threshold of 10–25% tree cover, while recognizing higher tree cover in the definition of tropical savannas. [Dixon et al. \(2014\)](#) and [Faber-Langendoen et al. \(2016\)](#) distinguished temperate savannas as those having 10% cover of trees < 5 m in height, from tropical savannas that have between 10% and 40% cover of trees < 8 m in height.

Woodlands are also described in several articles of this section, as these plant communities often occur among grasslands, savannas, and/or shrublands in a complex mosaic of different vegetation structural types and often share many ecological affinities and species with these adjacent communities. Woodlands are terrestrial ecosystems with a significant cover of trees but at lower densities than forests, often allowing enough sunlight through the canopy to support an abundant herbaceous or shrub ground layer of sun-loving plants. Where significant ecological similarities exist, woodland biomes are sometimes referred to as grassy woodlands or densely wooded savannas to highlight their relationships with grassy biomes ([Ratnam et al., 2011](#); [Rehwinkel, 2020](#)).

Grasslands and shrublands are often further defined through terminology that explain their ecological origins and persistence. Zonal grasslands and shrublands are those that occur in climates too dry (e.g., steppes) or too cold (e.g., alpine or arctic tundra) to support forests ([Dengler et al., 2014](#); [Török and Dengler, 2018](#)). These grasslands and shrublands are often referred to as climato-genic. Azonal and extrazonal grasslands and shrublands are those that persist due to edaphic (i.e., soil) conditions (azonal) or local climate extremes (extrazonal), sometimes in conjunction with disturbances, in regions and climates that otherwise support forests ([Dengler et al., 2014](#); [Török and Dengler, 2018](#)). Primary grasslands and shrublands are natural grasslands and shrublands that have formed spontaneously as a result of climate, soil conditions, and possibly a predominant natural disturbance regime. Secondary grasslands and shrublands are those that resulted from human land uses that converted previous natural vegetation types to anthropogenic, but semi-natural grasslands and shrublands (e.g., cleared forest, drained wetlands).

Despite being globally widespread and extensive, grasslands and shrublands are often regarded as among some of the least studied ecosystems on the planet ([Gibson, 2009](#); [Rundel et al., 2018](#)). They are also some of the most negatively impacted ecosystems from recent human activities. Several major temperate grassland regions of the world have been largely converted to industrial agriculture, most of the Mediterranean-type ecosystems coincide with rapid urban development due in part to the favorable weather, and tropical savannas of sub-Saharan Africa are succumbing to desertification due to intensifying human land uses and a warming global climate.

Scope of the Grasslands and Shrublands Section

The articles in this section of the *Encyclopedia of the World's Biomes* cover a wide range of the different grassland and shrubland ecosystems that occur across the globe, from grasslands, shrublands and savannas that occur on remote islands of Oceania, to the most extensive temperate grassland region in the world—the Eurasian steppe. However, they are by no means comprehensive of all the grassland, shrubland, and savanna ecosystems on planet earth (see below for a discussion on the major grasslands, shrublands and savannas of the world not treated in this publication). This section of the Encyclopedia includes articles from the tropical, temperate and Mediterranean climate type regions of the world. Not covered in this section are the herbaceous, succulent, or shrub dominated ecosystems of the world's major desert regions, herbaceous and shrub dominated wetlands, and the extensive areas of low shrub and herbaceous dominated vegetation of the arctic tundra above the Arctic circle and, to a smaller extent, the alpine zones at the tops of high elevation mountain ranges. Also not treated in this section are croplands and intensively managed grasslands consisting of pasturelands that are plowed and intentionally seeded with improved varieties of forage species.

Biogeography and Ecology

Grasslands and shrublands occur within nearly every temperate and tropical terrestrial region of the globe. They occur as broad ecotypes spanning large swathes of entire continents, such as the Great Plains grasslands and sagebrush shrub-steppe of North America or the tropical grasslands and savannas of sub-Saharan Africa, but also as smaller insular habitats among regions largely dominated by forests or deserts. Three main environmental factors explain the existence, development, and persistence of grasslands, shrublands, and savannas: climate, physical disturbance and soil conditions, all of which are described in detail below. Depending on the biome, the region, or the specific location, the role of each of these three environmental factors can vary from exclusive to highly interactive in determining the presence and extent of grasslands and shrublands. More often than not, two or more of these environmental factors intersect and act synergistically in producing conditions conducive for the development and maintenance of grasslands and shrublands. A fourth important factor at play that is touched upon throughout this overview is the evolutionary traits of the diagnostic plants that not only allow them to persist and proliferate in these environments but also reinforce disturbance regimes and structural characteristics that maintain areas as grasslands, shrublands or savannas (e.g., hemi-cryptophytic life form, below ground buds, epicormic sprouting, abundant post-fire germination, flammable resins, etc.).

Climate

One of the most important factors determining the global distribution of the major grassland, shrubland and savanna ecosystems of the world is climate, namely aridity in the form of low or highly seasonal annual precipitation and/or low humidity ([Lugo et al., 1999](#); [Bredenkamp et al., 2002](#); [Gibson, 2009](#)). In temperate and desert regions of the world, large grassland or grass-shrub

environments occur in drier regions, often towards the interior of continents not influenced by maritime climates. In cooler dry climates, these grasslands and grass-shrub ecosystems are referred to as steppes, whereas in warmer dry climates, they are referred to as desert grasslands and semi-arid shrublands. In moister climates, where annual rainfall is adequate to support woodlands and forest, periodic landscape scale fires are central to maintaining these areas as grasslands and shrublands. In tropical regions, relatively low annual rainfall is an important contributing factor to the existence of grasslands, shrublands, and savannas. However, in many tropical environments, fire appears to play a critical role in the maintenance of grasslands, shrublands, and savannas, with the abundance of C_4 grasses and their fine fuels aiding in promulgating fires.

Mediterranean type climates, that mainly persist in five major regions of the world (California, central Chile, the Cape Region of South Africa, southern and southwest Australia, and the Mediterranean Basin) present unique environmental conditions where grasslands, shrublands and woodlands are widespread and often floristically distinctive with high plant species endemism. These regions have a pronounced winter wet/summer drought climate. Due to their coastal positions on the western edge of continents that receive westerlies that reliably brings winter rain, allowing abundant plant growth in late winter and spring, and persistent summer time high pressure systems causing summer drought and high temperatures, these regions, with the exception of Chile, have been highly prone to wildfires for millennia. This has led to the development of vegetation and species persistence strategies that are highly adapted to drought and wildfire, most notably expansive evergreen sclerophyll shrublands, as well as savannas, grasslands, and broadleaf evergreen woodlands, with forest vegetation often restricted to more mesic and/or fire protected sites. The sclerophyll shrublands and woodlands that predominate in all five regions superficially appear very similar but are from often distinct or distantly related evolutionary lineages. All five Mediterranean climate type regions possess exceptionally high plant species diversity and are considered biodiversity hotspots.

Disturbance

While most natural grasslands and shrublands owe their origins and existence in large part to climate (i.e., seasonal drought), and in some cases to soil conditions (e.g., infertile soils, ultramafic geology, highly saline soils, or shallow soils), for many grasslands and shrublands their continued persistence and maintenance can be attributed to periodic disturbances. As alluded to above, the most important of these in many parts of the world are fire and, to a lesser extent, animal herbivory. This is particularly important in tropical savannas at locales where the monsoonal climate and seasonal precipitation patterns may otherwise favor the development of forest or woodland vegetation, but where a warm moist growing season that supports high biomass production is followed by a dry season accompanied by lightning (Keeley and Rundel, 2005). The presence of a continuous grass cover, with its annual accumulation of fine dry biomass (i.e., low fuel bulk density), is easily ignitable during dry seasons and can carry fires throughout the savanna or grassland and sometimes into neighboring vegetation types (Hoffman et al., 2012; Dantas et al., 2015; van Nes et al., 2018), thereby maintaining open, grass dominated vegetation. Summer rain along with intermittent dry periods and lightning ignited fires has a similar impact on many temperate grassland biomes. Shrublands in semi-arid or seasonally dry (e.g., Mediterranean type climate) environments, while not as readily flammable as grasses, can promulgate wildfires in a similar way through an extensive canopy of interlocking shrubs that, once ignited, can carry expansive fires that consume above ground biomass and eliminate trees.

Herbivory by large grazing animals plays a significant role in many grassy biomes, particularly where their populations are high or had been in the past. In some cases pastoralism with domesticated livestock has replaced the role indigenous ungulates had on grasslands and savannas. Herbivory exerts a considerable influence on the structure and species composition of the herbaceous layer and limits establishment of woody plants within grassy biomes. Both herbivory and fires influence species composition and contribute to the openness and grass dominance in these systems, however, these two consumers of biomass impact grassy biomes in different ways (Bond and Keeley, 2005; Gibson, 2009; Archibald and Hempson, 2016). The comparative importance and interactive effects of these two disturbances varies depending on the region and grassy biome where they occur.

Other types of disturbances can also be highly consequential for the maintenance of some grasslands and shrublands, such as in the case of periodic inundation through landscape level seasonal floods (in the Pantanal of central South America and the Zambesian flooded grasslands of central Africa) and, in mountainous areas, heavy snow loads and avalanches. Along major riverine systems, periodic flooding and river scour create and maintain open or non-forested vegetation types in otherwise forested landscapes. Another important disturbance that maintains some grasslands and shrublands are disturbances initiated by humans, through intentionally set fires, livestock grazing, and mowing, or through historic clearing for agriculture and present day abandonment. In addition, all aforementioned types of physical disturbance can contribute to grasslands and shrublands occurring as temporary successional stages in forests.

Soils

In distinct locations on earth large areas exist where soil conditions are so harsh to plant life that they largely override the influence of climate and favor the evolution and development of generally herbaceous, shrubby, and otherwise low statured non-forest species, ecotypes and vegetation cover. Still, dry climatic intervals and natural disturbance regimes (e.g., fires) can intersect and further promote the development and persistence of grassland and shrublands in such areas.

Large areas with exposed ultramafic geology (magnesium and iron rich rock often commonly referred to as serpentine) occur across the globe near present or ancient convergent plate boundaries where oceanic plates were pushed down into the mantle

and later thrust onto continental plates. Ultramafic derived soils are deficient in the essential plant nutrients phosphorus, potassium and calcium, have low calcium to magnesium ratios that inhibits calcium uptake resulting in weak cell wall development, and have high concentrations of phytotoxic minerals, particularly nickel and chromium (Alexander et al., 2007; Tashakor et al., 2013; Galey et al., 2017). Herbaceous or low statured woody growth forms are more advantageous to overcoming these limitations on plant growth and nutrient uptake. Regionally extensive exposures of ultramafic surfaces, such as those found in the Klamath-Siskiyou mountains in northern California and southwest Oregon, the Gaspé Peninsula of eastern Canada, New Caledonia, and Sulawesi in Indonesia, as well as smaller insular ones elsewhere, often support extensive grasslands, shrublands, savannas, and stunted woodlands whose floras are composed of species that specifically evolved to only occupy these harsh soil environments (serpentine endemics), as well as populations of adapted individuals of common species from the adjacent non-serpentine influenced, habitat generalist floras.

Hopper (2009) describes old, climatically buffered, infertile landscapes (OCBIL theory) that occur in southwestern Australia, South Africa's Greater Cape Region and Venezuela's Pantepui Highlands. These are land surfaces where rejuvenation through glaciation, volcanism, uplift and mountain building have been absent for tens to hundreds of millions of years and have been sufficiently weathered so that soils are nearly devoid of essential nutrients for plant growth, particularly phosphorus. Here again, unfavorable soil conditions lead to the development of grasslands, shrublands and woodlands while constraining development of forest vegetation. Many of these regions with either ultramafic geology or old infertile landscapes harbor some of the world's highest plant species richness, in part due to speciation and evolution of traits for persistence driven by soil infertility and toxicity, and in the case of OCBILs, though the retention of relic species and families from ancient lineages (i.e., paleo-endemics).

What these aforementioned environments have in common is that soil infertility (i.e., oligotrophic soils), and its resulting growth limitations and drought stress on plants, severely constrained the development of arboreal plant growth forms and instead favored herbaceous and lower statured woody plants that characterize grasslands, shrublands, savannas and woodlands. Furthermore, areas of high soil salinity, such as those found in endorheic drainage basins, support halophytic flora often in the form of succulent or scrub vegetation.

While not significant nurseries for the evolution of plant species as the environments mentioned above, excessively drained and highly mobile substrates such as sands on stabilized sand dunes, talus slopes, and pumice fields, as well as areas of shallow bedrock (e.g., limestone and dolomite grasslands of southeast United States) and salt spray influenced coastal fringes, similarly make tall tree and forest growth difficult and tend to support herbaceous, shrub, savanna, or low statured woodland communities.

Origins of Grasslands and Shrublands

While the early terrestrial biota of the earth following the evolution of large land plants (e.g., horsetails, ferns and gymnosperms) is often thought of as vast forests growing in a warm wet world, large areas of herbaceous and low statured woody vegetation may have existed as far back as the middle/late Triassic Period (230 Ma). At this time the vast continental interior of the supercontinent Pangea harbored the arid conditions, seasonality of rainfall, and resulting accumulation of dry biomass susceptible to wildfires that favored the evolution and expansion of herbaceous and low statured woody plants from among the ferns and gymnosperms (Bredenkamp et al., 2002). Fossil evidence also shows that fires were common during the earlier Permian and Carboniferous Periods (Falcon-Lang, 2000; Jasper et al., 2013) and may have affected the development of vegetation in similar ways.

Grasses and grasslands emerged only recently relative to other major plant lineages and biomes of the earth. The hemicyptophytic life form (i.e., herbaceous plants with perennating buds at or near the soil surface) that is so prevalent in contemporary grassland taxa evolved early in the monocotyledons in response to harsh environmental conditions. This important trait most likely originated in oxygen deprived aquatic habitats (Takhtajan, 1969), only later becoming advantageous to withstanding defoliating disturbances and drought. The common ancestor that gave rise to the Order Poales, which contains Poaceae (i.e., true grasses) as well as similar families such as Juncaceae, Cyperaceae and Restionaceae that also can form the major component species of grasslands, diverged in the middle Cretaceous Period more than 100 Ma (Janssen and Bremer, 2004). Early grasses evolved in forest environments under shade or in forest openings (Bredenkamp et al., 2002; Gibson, 2009). The early lineages of the two main clades that comprise the bulk of Poaceae emerged during the Eocene Epoch between 55 and 34 Ma, with fossil evidence pointing to an even earlier emergence of a component subfamily, Ehrhartoideae, in the late Cretaceous (Prasad et al., 2011).

The appearance of grasslands, extensive areas dominated by herbaceous angiosperms mostly in the family Poaceae and its related families, was largely associated with the spread of open habitats that formed when arid, or at least seasonally dry, conditions took shape over portions of continents. The first expansive grass-dominated ecosystems likely appeared in South America around the Eocene-Oligocene boundary 34 Ma (Coughenour, 1985; Jacobs et al., 1999). This expansion of grasslands continued through the Oligocene and by the Miocene Epoch (23–5 Ma), grasslands were globally widespread, occurring on all the large continents except for Antarctica (Stebbins, 1981; van der Hammen, 1983; Strömberg, 2002; Kamelin, 2017). It was during the mid-Miocene period that the major diversification of the grass family coincided with this widespread, worldwide development of grasslands (Kellogg, 2001).

Adaptation to drought appears to be the key development in grasses that allowed them to spread into these newly created open habitats that had been expanding during the Eocene and onward. Some of the most important of these traits, as summarized by Gibson (2009), include basal meristems, small stature, deciduous shoots, below ground nutrient reserves, and rapid transpiration and growth in response to irregular moisture availability. Ability to survive drought is often regarded as the main environmental

factor selecting for low stature in plants and the herbaceous habit is general. In grasses, this selection pressure has often come in combination with disturbances, such as animal grazing or trampling and fires, that defoliate and otherwise destroy above ground biomass of individual plants. The intercalary meristem, which allows growth from both the base of leaves and internodes of stems, is also an important trait that evolved in grasses, allowing them to respond to defoliation by wildfires or herbivory.

Although grasses existed for a long time before large mammalian grazing ungulates evolved, there is a strong conjunction between the emergence of a diverse array of large grazing mammals with hypsodont teeth and the widespread expansion of grass dominated ecosystems (Stebbins, 1981; Coughenour, 1985). Their emergence coincided so closely that it is widely regarded as an example of co-evolution, with the grazing by these animals reinforcing the spread and maintenance of grasses and grasslands.

Another important development within the evolutionary history of the grasses, as well as the spread of grasslands, is the evolution of C_4 photosynthesis. C_4 photosynthesis evolved independently and multiple times in several eudicot and monocot plant lineages in response to arid climate conditions, with a significant proportion of these C_4 lineages emerging from within a portion of the Poaceae family. C_4 photosynthesis is therefore considering one of the most overwhelming examples of convergent evolution among life on earth (Sage et al., 2011). It is a metabolic pathway that, through the process of concentrating CO_2 in bundle sheet cells, allows the plant species that possess it to maintain a high photosynthetic rate while stomata are nearly or entirely closed. This affords these plants considerable water conservation abilities, while allowing them to produce considerably higher biomass under high temperatures and arid conditions than they otherwise could. This ability was highly consequential for the expansion of grasslands during the late Miocene. Climate changes during this time brought about drier conditions (including monsoonal summer rainfall and abundant lightning), throughout large portions of the tropical and sub-tropical regions of the world (Keeley and Rundel, 2005; Bond, 2015). The C_4 grasses that existed in these regions were well suited to take advantage of these climate conditions, and they produced high amounts of biomass during the wetter portions of the year that were then easily ignited during the drier periods. This resulted in the rapid, wildfire facilitated spread of grassland and savanna environments throughout the tropical and subtropical regions of the world during the late Miocene (Keeley and Rundel, 2005), because this process not only reinforces the maintenance of large grassland and savanna environments, but also allows their expansion into areas that would otherwise support forests (Keeley and Rundel, 2005; Hoffman et al., 2012; Bond, 2015; van Nes et al., 2018).

The appearance of widespread shrubland biomes on earth is potentially far more difficult to ascertain within the geologic record than is the arrival of grasslands. This is because of the considerable variability in plant growth forms within plant families and their lineages, particularly in the angiosperms, and because the component low statured woody taxa are derived from a large number of angiosperm lineages that also include tall woody taxa. Therefore, it is difficult to determine the presence of widespread shrublands from limited fossil evidence such as pollen or small fossilized remains, as compared to the relative ease of identifying the pollen and fossil signatures of just a few characteristics plant lineages (i.e., Poaceae) that indicate the first arrival and widespread presence of grasslands.

However, many of the same extreme environmental pressures that drove the development of the first grasslands (i.e., arid or semi-arid climate, fires, grazing and trampling by large animals) very likely resulted in the spread of shrubland ecosystems, and they could conceivably have appeared much earlier in the earth's history than did grasslands. Additionally, the advantage that small-statured woody plants have over tall woody plants to persist on shallow or nutrient poor soils would have made possible the existence of shrublands over these edaphic controlled areas. Possessing a low stature affords a considerable advantage in meeting evapotranspiration evaporative demand when exposed to periodic or persistent drought as compared to the high water demand involved with maintaining a tall structure. Therefore, it is likely that low statured woody plants formed shrublands and low statured woodlands in arid and semi-arid environments after species from the regional species pool evolved the ability to persist and spread through those environments.

Furthermore, most angiosperms possess the ability to re-sprout from above ground or below ground parts following exposure to environmental stresses that damage or destroy above ground biomass, whereas gymnosperms (conifers) rarely have this trait. In most angiosperms, dormant, protected, or adventitious buds are grown during a plant's development or are later differentiated from superficial tissue that allow sprouting from stems through epicormic buds. Re-sprouting of the whole above ground plant body can also occur from re-sprouting stumps or below ground lignotubers. New meristem growth, initiated by low auxin and high cytokine levels (i.e., death of the terminal end of a stem), readily commences from these pre-existing or newly created buds, enabling the surviving part of the plant to recover from damage or loss to above ground biomass. While it is unclear whether these re-sprouting traits evolved in response to drought or disturbance (Hopper, 2009), they are certainly strategies of resistance against loss of biomass and are critical traits that allow woody angiosperms to survive defoliation from herbivory, wildfire, and other destructive above ground disturbances (Zeppel et al., 2014). Woody plants that possess strong re-sprouting abilities can proliferate in areas with regular disturbances. Plant species with strong re-sprouting abilities and other persistence strategies coupled with a low stature, can also reinforce disturbance regimes such as fire, thereby maintaining areas of shrubland and low statured woodland. Exemplars of this can be found in the evergreen sclerophyll shrublands and woodlands that predominate in the Mediterranean type climates of the world (California, the Mediterranean Basin, central Chile, the Cape Region of South Africa, and southern and southwest Australia). While these shrubland and woodland communities are profoundly shaped by this distinct Mediterranean type climate regime, which appeared in its present day locations during the Miocene (Rundel et al., 2016), there is a great deal of evidence that evergreen sclerophyll vegetation existed much earlier than the onset of Mediterranean type climates and under different climate conditions, being particularly widespread across North America and Southern Eurasia (Madrean-Tethyan regions) during the Eocene Period (Axelrod, 1975; Valiente-Banuet et al., 1998; Verdú et al., 2003). Many modern Mediterranean plant clades in California, the Mediterranean Basin, and central Chile diversified in the Miocene following the onset of Mediterranean

type climates (Rundel et al., 2016, 2018; Vargas et al., 2018), whereas the South African Cape Region and southwest Australia possess many older lineages (Hopper and Gioia, 2004; Carpenter et al., 2015).

During the Cretaceous Period, evergreen sclerophyll shrublands existed on oligotrophic soils and other challenging soil conditions that some authors have termed “edaphic ghettos” (very shallow soils, heavy clays, etc.). These soil conditions limited tree growth at a time when warm humid climates mostly supported forests worldwide (Rundel et al., 2016). However, molecular-dated phylogenies and fossils of the currently extant fire adapted family Proteaceae, which contains a great deal of shrub and low statured tree species, show the appearance of strongly fire adapted traits in the late Cretaceous (Lamont and He, 2012; Carpenter et al., 2015). This evidence of strongly fire adapted species suggests that fires, and therefore fire sculpted shrublands and woodlands were somewhat common and not only restricted to edaphic controlled areas during this time period, at least in parts southern Africa and Australia. Fires were common over portions of the globe during the Cretaceous Period (Bond, 2015) and therefore it is probable that expansive shrublands were also prevalent.

Shrublands may have lost ground to forest in the still warm and humid climate of the Eocene when fire activity diminished considerably, becoming restricted to resource poor or shallow substrates, dry interiors of continents, and areas of frequent river scour. But, there was a marked increase in fire activity in the mid to late Miocene (Bond, 2015) and at the same time there was an ongoing cooling and drying climate, which had been occurring throughout the Tertiary Period. These conditions once again promoted the formation or expansion of widespread shrublands, and by this time grasslands as well. These global trends in climate and fire activity have continued to the present day.

The origins of present day grasslands and shrublands are likely different wherever they currently exist across the globe. However, most will owe their origin to the widespread occurrence of drought and fire. As a general pattern, many modern day grassland and shrubland biomes had their beginnings in the Tertiary Period as an increasingly cooler and arid climate took shape over large portions of the planet in the Paleogene and Neogene Periods and continuing to this day, and expanded significantly as fires became much more prevalent across the globe roughly 10 Ma (Bond, 2015). The position of the continents and distribution of arid and semi-arid climates, and therefore early analogs to present day grasslands and shrublands, began to settle in their current locations in the late Miocene and Pliocene. However, most present day grassland and shrubland biomes, particularly those in the higher (and therefore less climatically buffered) latitudes, developed during the more recent Quaternary Period.

Important Grasslands, Shrublands and Savannas Not Covered in This Section

The articles in this Grasslands and Shrublands section of the *Encyclopedia of the World's Biomes* largely cover the array of grassland, shrubland and savanna ecosystems that occur across the northern hemisphere. However, some types are missing from the southern hemisphere. A few important grassland, shrubland and savanna biomes from South America and Australia are not included and, except for the Mediterranean Basin region of northern Africa and the temperate grasslands of southern Africa, the vast diversity of grasslands, shrublands, and savannas of Africa are largely uncovered. I describe those missing types briefly in the following section.

Africa contains the most extensive area of tropical savannas of any continent on earth and otherwise possesses a wide array of dry woodlands, bushlands, temperate and montane grasslands, and Mediterranean scrublands. It is therefore regrettable that so few chapters on Africa's grasslands, shrublands and savannas are presented in this section.

Tropical savannas are very widespread across Africa, covering roughly 50% of its land area (Shorrocks and Bates, 2015). The vegetation composition therefore varies considerably between the different regions where they occur. The Sahelian and Sudanian savannas, characterized (often sparsely so) by trees in the *Acacia* genus to the north and *Combretum* and *Terminalia* shrub and tree species to the south, stretch across sub-Saharan Africa south of the Sahara desert and north of the Equatorial forest regions. In the east, the tropical savanna biome wraps around the Congo and Lake Victoria Basins going south through East Africa in the form of the *Acacia* and *Commiphora* tree and shrub savannas and bushlands that spread across the Horn of Africa countries and southward through Kenya and Tanzania. This region includes the Masai xeric grasslands in Kenya and the iconic Serengeti grasslands in Tanzania. South of the Congo rainforests, throughout much of southern Africa north of the deserts and temperate region, are the Miombo and Mopane savannas and woodlands, two extensive vegetation types broadly defined by the dominance of miombo (*Brachystegia boehmii*) and mopane (*Colophosphermum mopane*) trees respectively. Shorrocks and Bates (2015) provide a thorough treatment of the tropical savanna biome of Africa, while Scholes and Walker (1993), and White (1983) also offer useful overviews.

There exists several good references for the vegetation of southern Africa that include descriptions of the region's grasslands, savannas and shrublands not already covered in this section, including Cowling et al. (1997), Born et al. (2007), Mucina and Rutherford (2006), and Bergh et al. (2014). Dean and Milton (1999) provide an in-depth treatment of the extensive Karoo shrubland biome of southern Africa. Cowling and Pierce (1999) give a detailed description of a component of the Karoo biome known as Namaqualand, or Succulent Karoo. In addition, Cowling and others (Cowling, 1992; Cowling and Richardson, 1995; Rebelo et al., 2006) provide several thorough accounts of the South African Cape Mediterranean Scrub, collectively the Fynbos and renosterveld, the only one of the five Mediterranean climate type shrubland biomes not covered in this section. Another unique shrubland of the South African Cape, Albany thickets, are described by Cowling et al. (2005) and Hoare et al. (2006). Jacobs and Schloeder (2002), Williams et al. (2004), and Kidane et al. (2012) are all suitable references for understanding the montane grasslands of Ethiopia. An introduction to the grasslands and dry thickets and woodland of Madagascar can be found in Vorontsova et al. (2016), Gautier and Goodman (2003), and Koechlin (1972).

There are many articles in this section from South America that cover a great deal of the continent's grassland, shrubland, and savanna vegetation cover. However, due to its great topographical diversity and latitudinal span, several important grasslands and shrublands were missed. [Veblen et al. \(2007\)](#) give overviews of the major regional environments of the continent. Within this volume [Rundel et al. \(2007\)](#) and [Paruelo et al. \(2007\)](#) cover the Monte region and the Patagonian steppe respectively. [Gaitán et al. \(2020\)](#) also describe the vegetation of the Monte and Patagonian steppe in the Deserts section of this Encyclopedia. [Young et al. \(2007\)](#) describe the alpine and montane shrubland, sub-shrub, and grassland communities of the puna, páramo and southern Andean steppe found in the northern and central Andes. Further information on these ecosystems can be found in [Villagrán et al. \(1981\)](#), [Carilla et al. \(2018\)](#), and [Lambrinos et al. \(2006\)](#). In the central lowlands of Venezuela and Colombia lies a significant tropical grassland and savanna biome known as the Llanos that is described in [Blydenstein \(1967\)](#), [Medina and Silva \(1990\)](#), [Ramia \(1967, 1974\)](#), [Behling and Hooghiemstra \(1999\)](#), and [Berroterán et al. \(1998\)](#). [Larrea-Alcázar et al. \(2011\)](#), [Langstroth \(2011\)](#), and [Haase and Beck \(1989\)](#) give focused treatments of the Beni savanna of northeast Bolivia.

In Australia, not covered in this section of the Encyclopedia are the semi-arid shrublands and spinifex grasslands that cover vast portions of the interior of the continent and its central west coast south of the tropical regions. The book by [Keith \(2017\)](#) provides an overview of these vegetation formations, as well as a review of all of Australia's vegetation. It also presents a comprehensive account of all the heathlands of Australia ([Lamont and Keith, 2017](#)) that includes the heath communities not treated in the articles in this section. In addition, [Keith \(2017\)](#) covers the montane grasslands of the Australian Alps. Also from this part of the globe, [Mark and others \(Mark, 1993; Mark et al., 2013\)](#) describe the prominent montane and temperate grasslands of New Zealand's South Island.

Introduction to the Grasslands and Shrublands Chapters

The Grasslands and Shrublands section is organized by the continents and as best as possible covers the major grassland, shrubland, savanna and steppe ecosystems from all the continents of the globe, including Oceania and excluding Antarctica. Tropical, Temperate, and Mediterranean Grasslands of the World ([Faber-Langendoen, 2020](#)), which includes descriptions of savannas and most shrubland ecosystems, starts off the section by providing a global overview through the lens of The International Vegetation Classification.

For North America, [Comer and Hoagland \(2020\)](#) describe the temperate grasslands of the Great Plains and Chihuahuan Desert that stretch from central Canada to northern Mexico. The grasslands and savannas of the southeastern United States are reported on by [Noss \(2020\)](#). [Parker \(2020\)](#), [Tyler and Stahlheber \(2020\)](#), and [Dunwiddie and Alverson \(2020\)](#) provide overviews of the chaparral of California, the oak savannas and grasslands of California, and the prairies, savannas, and oak woodlands of the Pacific Northwest, respectively. In the North American western interior, [Shinneman \(2020\)](#) gives an account of the North American sagebrush steppe and shrubland, while [Muldavin and Triepke \(2020\)](#) cover the Pinyon-Juniper Woodlands. Lastly, [Valiente-Banuet and Verdú \(2020\)](#) discuss the Mexical shrubland of central Mexico with a special focus its ancient relationship with the modern evergreen sclerophyllous vegetation of several Mediterranean climate-type regions of the world.

Moving to South America, [Silva and Lacher \(2020a,b\)](#) present two chapters, one on the savannas of the Cerrado and the other on the Caatinga woodlands, which together cover a great deal of the eastern half of Brazil. [Fernández et al. \(2020\)](#) summarize the grasslands and open savannas of the Dry Chaco of northern Argentina, southern Bolivia and western Paraguay, while [Oyarzabal et al. \(2020\)](#) cover the temperate subhumid grasslands that surround the Río de la Plata estuary in central-eastern Argentina, Uruguay and southern Brazil. [Meserve et al. \(2020\)](#) describe the Mediterranean-type shrubland of central Chile, known as the Chilean matorral, along with the neighboring thorn scrub communities to the north.

[Vargas \(2020\)](#) discusses the Mediterranean floristic region, which covers the Mediterranean Basin (southern Europe, northern Africa, and western parts of the Middle East and Asia Minor), touching on explanations for its exceptionally high diversity of plants.

Dr. Jürgen Dengler and Dr. Peter Török very graciously organized 13 articles for this section from multiple author teams from across Europe and Asia on the various grasslands and shrublands of the Palaearctic Realm (encompassing the temperate regions of Europe and Asia as well as North Africa) on behalf of the European Dry Grasslands Group (<https://edgg.org/>). They present a comprehensive and unifying overview of the Palaearctic grasslands and shrublands ([Dengler et al., 2020b](#)) and introduce the following chapters from Palaearctic Realm: Grasslands and shrublands of the Mediterranean Region ([Guarino et al., 2020](#)), Heathlands of temperate and boreal Europe ([Loidi et al., 2020b](#)), Shrublands of temperate Europe ([Loidi et al., 2020a](#)), Grasslands of Western Europe ([Boch et al., 2020](#)), Grasslands of Northern Europe and the Baltic countries ([Dengler et al., 2020a](#)), Grasslands of Eastern Europe ([Török et al., 2020](#)), Grasslands and shrublands of the Middle East and the Caucasus ([Ambarli et al., 2020](#)), Grasslands and shrublands of Russia ([Tishkov et al., 2020](#)), Grasslands and shrublands of Kazakhstan and Middle Asia ([Wagner et al., 2020](#)), Grasslands and Shrublands of Mongolia ([Pfeiffer et al., 2020](#)), Grasslands of China ([Li et al., 2020](#)), and Grasslands and shrublands of Japan ([Ushimaru et al., 2020](#)).

For the subtropical and tropic regions of Asia, [Wikramanayake et al. \(2020\)](#) present the chapter on grasslands and savannas of South Asia. [Brown and Bezuidenhout \(2020\)](#) provide a treatment of the temperate grasslands of southern Africa.

[Woinarski et al. \(2020\)](#) provide an overview of the tropical savannas of northern Australia while [Rehwinkel \(2020\)](#) outlines the South-eastern Australian temperate grasslands and grassy woodlands. The Mediterranean climate-type shrubland ecosystems of Australia are treated in two separate chapters: Sclerophyll shrublands of southwestern Australia ([Lamont, 2020](#)) and Mallee and maalok ecosystems of southern Australia ([Keith et al., 2020](#)). Representing Polynesia and Micronesia, several teams of United States

Fish and Wildlife Service scientists describe Hawai'i's dry, wet and mesic grasslands and shrublands (Pe'a et al., 2020; Nelson et al., 2020; Ball et al., 2020, respectively), as well as the savannas of the Mariana Islands Archipelago (Frager et al., 2020).

As stated above, the articles in this Grasslands and Shrublands section of the *Encyclopedia of the World's Biomes* are by no means a comprehensive accounting of all the grassland, shrubland, savanna and steppe ecosystems that currently exist on earth. The diversity of these habitats is as vast and variable as their distributions across the planet is broad. However, these articles provide a starting point for individual students and researchers to discover and build their knowledge of these important ecosystems, as well as the context and framework for the continued exploration, inquiry and scientific research of the grassland and shrubland biomes of the globe.

Abstract

Grasslands of the world span the tropics to temperate regions. We first define grasslands in general, then we use the International Vegetation Classification (IVC) to characterize the vegetation, climate, soils, disturbances and geographic range of the four major grassland biomes (IVC formations): Tropical Lowland Grassland, Savanna, and Shrubland, Tropical Montane Grassland and Shrubland, Mediterranean Scrub and Grassland, and Temperate Grassland and Shrubland. We recognize 54 biogeographically based continental grassland biomes (IVC divisions) and summarize their spatial distribution by WWF ecoregions. We highlight various patterns of grassland productivity, ecosystem services and climate change. In conclusion, we briefly describe a number of tools that can assist the conservation of these critically imperiled biomes.

Introduction

Natural grasslands may, at a casual glance, seem somewhat monotonous and simple, little different than an overgrown pasture, or easily replicated by planting. Yet a closer look shows a diversity of species that reach up to the sun and quiver in the wind, flatten with rain, disappear in a fire, slump through winter, and reemerge fresh in the spring. And unlike almost any other system, grasslands contain large animals that tower over the system they are in, introducing plant-animal dynamics rarely found in other biomes. Indeed, in what other biome would Aldo Leopold's quote be so applicable, as he wondered "what a thousand acres of silphiums looked like when they tickled the bellies of the buffalo."

Here we introduce in broad strokes the major grassland (including savanna) biomes that comprise a large portion of the globe. We focus on four major global grassland biomes: Tropical Lowland Grassland, Savanna, and Shrubland, Tropical Montane Grassland and Shrubland, Mediterranean Scrub and Grassland, and Temperate Grassland and Shrubland. We then turn to look at the diversity within these biomes across and within continents. We conclude by briefly describing some important aspects of grasslands, including their productivity, ecosystem services, climate change and conservation.

Defining Grasslands—An Ecological Vegetation Perspective

Following [Dixon et al. \(2014\)](#), we define natural or semi-natural grassland by the following typical characteristics:

1. a non-wetland, natural formation,
2. vascular vegetation has at least 10% cover,
3. graminoids have at least 25% cover (but if <25% cover, graminoids exceed that of other herbaceous and shrub cover),
4. broad-leaved herbs (forbs) may have variable levels of cover and dominance,
5. shrubs have <25% canopy cover,

6. and trees:

- (i) in temperate zones, typically have <10% canopy cover, are <5 m tall and single-layered,
- (ii) in tropical regions, typically have <40% canopy cover, are <8 m tall, and single layered.

Several aspects of this definition deserve additional comment (see also [Dixon et al., 2014](#)). First, the term “grassland” often has a broad meaning when defining a comprehensive set of ecological vegetation types (such as grassland versus forest, desert, tundra, or wetland). In this context, the grassland biome concept emphasizes dominance by grasses or grass-like plants (graminoids) and the lack of trees, but also includes other narrow-leaved grass-like herbs (i.e., non-woody graminoids) and even forbs (broad-leaf herbs) ([Veldman et al., 2015](#)). In his comprehensive review of major grasslands regions of the world, [Coupland \(1979\)](#) defined “grassland” as referring to “ecosystems in which the dominant vegetation is comprised of herbaceous species.”

From a biome perspective, natural grasslands are typically separated from other related types, including cultural grasslands, wetlands and woodlands. For example, the *Ecosystems of the World* project provided separate descriptions for natural grasslands ([Coupland, 1992](#)) and managed grasslands ([Breyer, 1987–1990](#)). Grassland often form an ecotone with woodlands. Our thresholds for distinguishing grasslands from woodlands are adapted to tropical and temperate conditions (see [Dixon et al., 2014: Table 1](#) for a comparison between American and African definitions). We reserve the term savanna for tropical grasslands, with or without a scattered woody layer, but not sufficiently dense or tall to qualify as woodland. Grasslands grade into wetlands which are characterized by wetland growth forms (including aquatic plants, forbs, and mosses) that comprise various open wetland biomes, such as ponds, bogs, fens, salt and freshwater marshes.

We limit our review here to Tropical, Temperate and Mediterranean Grasslands, the most common and dominant of grassland types. Grassland-dominated stands can also occur in deserts and in alpine or tundra biomes, and they are described elsewhere.

Types of Grasslands

We present four major biome types, following our grassland types defined in the International Vegetation Classification:

- Tropical Lowland Grassland, Savanna, and Shrubland
- Tropical Montane Grassland and Shrubland
- Mediterranean Scrub and Grassland
- Temperate Grassland and Shrubland

We include shrublands in the name of the types, because even though they are typically a relatively minor component at higher hierarchical (biome-scale) levels, they may form distinct plant community types at lower levels.

Tropical Lowland Grassland, Savanna, and Shrubland

Summary: Tropical Lowland Grassland, Savanna & Shrubland is characterized by shrubs and herbs with mesomorphic growth forms (including *broad-leaved*, *small-leaved*, *sclerophyllous*, and *palm shrubs*, and *forb* and *graminoid herbs*). Annual precipitation is seasonal to monsoonal and typically varies from 50 to 150 cm. In the driest climates, the herbaceous cover is annual and/or sparse. Vegetation structure varies from open grasslands, with very few woody growth forms to closed-canopy shrubland. Spatially patchy vegetation structure is typical for this type, especially the savannas with clumped or irregular horizontal canopy spacing and variable height. Neotropical and paleotropical savannas are included here as well as lowland shrublands or scrub, such as the Neotropical Cerrado. Savannas represent the vast majority of the area covered by this type and they are characterized by a layer of perennial herbaceous plants, mainly C₄ grasses and sedges, and C₃ forbs, with varying degrees of shrubs, and with low trees (<8 m) ranging up to 40% cover. This type is found widely throughout lowland and montane habitats of the tropical latitudes, from the equator to about 23°N and S ([Whittaker, 1975](#); [Woodward, 2008](#); [Faber-Langendoen et al., 2016](#)).

Climate: This formation occurs typically within an annual precipitation range of 100–150 cm, with lower and upper extremes around 40 and 200 cm, respectively. The rainfall is seasonal, with either a short (1–3 months) dry season or a long one (5–7 months). Mean annual temperature is about 22–25 °C but can reach 6 °C in winter at the edges of the tropical distribution range (e.g., southern limit of Cerrado in Brazil), with very occasional frosts. Even though a close correlation exists between tropical savannas and the Tropical Wet and Dry Climate (Aw in the Koeppen climate classification system), climate does not seem to be the main reason most savannas are found where they are; rather, as [Woodward \(2008\)](#) notes, “repeated burning, low-nutrient soils, iron-rich hardpans close to the surface, and the impacts of large grazing and browsing mammals are also factors in the presence and maintenance of many of the world’s tropical grasslands.”

Soil/substrate/hydrology: Tropical savanna usually develops on nutrient-deficient, acidic soils (Oxisols, Ultisols) with aluminum toxicity and pronounced alternation of wet and dry conditions. Soils in humid tropical climates are exposed to high rates of leaching, and the amount of leaching is related to the age of the land surface. Thus, in Brazil and western Africa, the savannas lie on very ancient surfaces that for millions of years have been affected by high temperatures and relatively high amounts of rainfall, whereas over much of eastern and southern Africa, the savannas lie on younger, less leached surfaces, and soils are less acidic (pH = 6.2) and

Modified from the Dixon, A., Faber-Langendoen, D., Josse, C., Morrison, J. and Loucks, C.J. (2014). Distribution mapping of world grassland types. *Journal of Biogeography* 41, 2003–2019. publication by John Wiley and Sons.

somewhat more fertile. Savannas that flood seasonally are common in the tropics, especially in South America (the Llanos, Beni, and Pantanal). There they occur in a complex spatial mosaic of upland and seasonally flooded types, with waterlogged soils grading into drained soils within very short distances. (Woodward, 2008).

Natural disturbances: Fires play a critical role in tropical grasslands and, whereas drought may prevent tree establishment in part of the savanna range, fires may override climatic conditions favorable to tropical woodlands and forests in other parts of the range (Bond et al., 2005). Lightning is the most common source of natural fires, but humans have long played a role in increasing the fire frequency throughout the tropics.

Animals: The role of large animals in savanna structure and function can be quite substantial. For example, in eastern and southern Africa, herds of large mammals are conspicuous, including zebras (*Equus* spp.), wildebeest (*Connochaetes taurinus*), antelope (*Hippotragus equines*), elephant (*Loxodonta africanus*), rhinoceroses (*Diceros bicornis* and *Ceratotherium* spp.), and giraffes (*Giraffa* spp.). But elsewhere, the most characteristic animals may be small mammals, including rodents, rabbits, and hares. Though not typically seen, termites (*Macrotermes* spp.), play a substantial role in savanna soil processes, and are conspicuous through their above ground mounds or termitaria (Woodward, 2008).

Human disturbances: Humans have had a long history in shaping tropical savannas. In tropical southeast Asia and India, savannas are most likely derived from human activities such as logging, burning, and the grazing of livestock, any or all of which altered tropical dry (or deciduous) forests that once grew in the area (Woodward, 2008). Caribbean pine savannas have a more complicated history, with stands being derived from both natural and human processes.

Geographic range: This formation type, or biome, is found in northern South America, western and southwestern Amazon Basin, Guiana Shield, Brazilian Shield, Western Africa (Guinea-Congolia/Sudania regional transition zone), sub-Sahel (Sudanian regional center of endemism), the Central African Plateau (Guinea-Congolia/Zambezia regional transition zone and the Zambezan regional center), and Eastern Africa (Somali-Masai regional center of endemism), northern Australia and Indomalaysia. It is typically located poleward of the Tropical Rainforest and Tropical Dry Forest biomes and form a transition between those forests and the deserts of the subtropics. The boundary between forest and savanna is often abrupt.

Tropical Montane Grassland and Shrubland

Summary: Tropical Montane Grassland & Shrubland is dominated by shrubs and herbs with mesomorphic growth forms, predominantly tussock grasses, large rosette plants, shrubs with evergreen coriaceous and sclerophyllous-*ericoid* leaves, and cushion plants. Vegetation structure varies from grasslands, with few short woody growth forms, to a closed canopy of shrubs usually not taller than 1–2 m high. Spatially patchy vegetation structure is typical due to both substrate heterogeneity and human influence characterized by periodic burning and grazing. The majority of the area covered by this vegetation corresponds to types that occur on tropical mountains within or above the limit of continuous, closed-canopy forest or forestline and below the sub-nival elevations, from

3000 to 4500 m (i.e., *páramo* and *puna*). Annual precipitation varies with the site and aspect of the location, from 50 to 300 cm, and seasonality is related to the rainfall rather than to temperature. The main environmental difference between this formation and its temperate counterpart is the diurnal fluctuation of temperature, which can be of 20 °C or more in tropical high mountains (e.g., Andes, Africa), with no growth limiting season. Shrub and herbaceous vegetation of smaller tropical ranges (e.g., Central America, Southeast Asia and New Guinea) and on the summits of mountains of the Guyana Shield and the Brazilian *planaltos* (plateaus) are included here because they occur above the forest line (about 1600 m in the latter). True cryomorphic vegetation, super-*páramo* and higher elevation *puna*, are treated in the tropical alpine biome. They grow above 4300 m elevation up to the permanent snowline, with mean annual temperatures < 3 °C, and soils have cryomorphic features (such as cryoturbation). Physiognomic distinctions are mostly based on the ground, which is continuous here as compared to the low, semi-open coverage of the tropical alpine biome.

Climate: The majority of the area covered by this vegetation corresponds to types that occur on tropical mountains near or above the limit of continuous, closed-canopy forest or forestline and below the sub-nival elevations, from 3000 to 4500 m (i.e., *páramo* and *puna*). The elevational range varies depending on the location, but it is the correlation between elevation and a decrease in temperature that, in natural conditions, generates the replacement of forested vegetation with grasslands and shrublands. There are other factors, such as the effect of recent glaciation periods, and anthropogenic disturbance. The variability in elevation range is associated with greater variation in climate among locations, but in general, the mean annual temperature for this type is between 3° and 12 °C, with lower locations reaching a maximum of 18 °C average annual temperature. The greatest fluctuation in temperature occur daily rather than seasonally. Due to the mountain setting, precipitation is highly variable as well, both in the annual amount and the distribution, with some locales having a marked dry season and others more humid throughout the year.

Soil/substrate/hydrology: Given the volcanic origin of several tropical mountains, they have volcanic ash soils, with very high organic content and a high water-holding capacity. Other uplifts have formed metamorphic, sandstone or limestone ranges, with soils varying from shallow to deep, highly humic and forming clayish peat in locations with permanently high moisture.

Geographic range: Tropical Montane Grassland & Shrubland occurs in the tropical mountain regions of Central and South America, Africa, Malaysia, including New Guinea, Hawaii, lower ranges in the Caribbean, and Brazil.

Mediterranean Scrub and Grassland

Summary: Mediterranean Scrub and Grassland includes sclerophyllous scrub and herbaceous vegetation that develops in (moderately dry, warm-temperate, maritime climates with little or no summer rain). It occurs in the Mediterranean Basin, southwestern California in the United States, west-central Chile, the western Cape Province of South Africa, and southwestern and southern Australia. Sclerophyll-leaved growth forms prevail, but facultatively drought-deciduous “soft chaparral” forms may also occur. Mixed annual and perennial grasslands and non-grass “forblands” may also occur, with only scattered scrubby trees and shrub. Shrub growth forms range from low, open subshrubs (< 1 m) to arborescent (2–5 m tall) shrubs with a closed canopy, in response to moisture, fire and other factors. Dominant plants are affected by frequent fires, except for in Chile. Sclerophyll woodlands and forest are excluded from this classification of Mediterranean Scrub and Grassland. Grasslands are a mix of annual and perennial growth forms. (Whittaker, 1975; Faber-Langendoen et al., 2016).

Physiognomy and structure: There is a complex variation of growth forms, depending on the interactions of rainfall, soil texture, and type and intensity of natural processes such as fire, browsing/grazing, and bioturbation. Broad-leaved evergreen, sclerophyllous shrubs dominate the vegetation in areas with higher and more predictable winter rainfall, while facultatively deciduous shrubs occur in areas that are drier and rainfall is less predictable. Perennial herbaceous vegetation such as bunchgrasses occur in areas with relatively high precipitation. Perennial geophytes (bulbs, corms, etc.) are especially common in South Africa. Above-ground portions of perennial grasses dry and wither, or annuals set seed and die by mid-spring to early summer. Small numbers of summer annuals also occur, which take advantage of lingering deep soil moisture by having evolved long taproots. The vegetation tends to produce the highest biomass in the cool rainy winter and becomes dormant in the summer drought.

Climate: The Mediterranean climate is characterized by dry summers and mild, humid, sometimes rainy winters. Annual precipitation averages 25–100 cm. Freezing temperatures are relatively rare. Wherever mountains and predominant wind directions cause orographic effects (for example the rainfall increases on the windward side), and annual precipitation at the higher elevations may be sufficient to support a change from scrub to woodland or forest. With increasing latitude, rainfall totals and length of the rainy season also increase, causing a comparable shift to woodland or forest (Kuennecke, 2008). Many Mediterranean climate areas have been “invaded” by exotic annual grasses and other species that can modify natural disturbance patterns such as fire (Faber-Langendoen et al., 2016).

Geographic range: This formation or biome occurs in the Mediterranean Basin, and in the Mediterranean climate regions of southwestern California in the United States, west-central Chile, the western Cape Province of South Africa, and southwestern and southern Australia, at latitudes between 31° and 46°N in the Northern Hemisphere and between 28° and 42°S in the Southern Hemisphere. These areas form on the western or southern margins of continents where warm-season high pressure tends to settle offshore driving all precipitation to the north or south of the adjacent shore areas. Each region of Mediterranean scrub has developed unique names for the type, including in California, *chaparral* and *coastal scrub*; in Chile, *matorral* and *espinal*; in Spain, *tomillares*; in France or French-speaking countries, *maquis* or *garrigue*; in Greece, *phrygana*; in Israel, *bath’a* or *goresh*; in South Africa, *fynbos* and *strandveld*; and in Australia, *kwongan* and *mallee* (Kuennecke, 2008).

Temperate Grassland and Shrubland

Summary: Temperate grasslands are dominated by mesomorphic to somewhat xeromorphic perennial grasses with a variable amount of perennial forbs. Trees are scattered to largely absent (typically <10% cover), often controlled by drought, cold or fire. Grasses and forbs grow to different heights at maturity, depending on climate, soil and other factors. Grasses may be either tussock (bunch) forming or sod forming (forming a carpet on the ground), with bunchgrasses increasingly common in droughty conditions. Both C3 and C4 grasses are found, with C3 increasingly common toward the poles. Grasses and perennial forbs are well-suited to withstand cold seasons and tolerate grazing and fire because of the position of their buds near or below the ground surface.

Climate: Temperate grasslands occur in regions with a semi-arid to moist climate (mostly BSk in the Koeppen climate classification). Semi-arid climate regions receive 25–50 cm of precipitation a year; moist regions receive 50–90 cm. Snow may occur in some areas, including mid-continental prairie of North America and the East European steppes of Eurasia. The continental location of grasslands in both North America and Eurasia creates wide annual range in temperatures, with winters having temperatures well below freezing and summers very hot, and the growing season extending from 5 to 7 months (Woodward, 2008).

Continental precipitation gradients shape the distribution of regional temperate grassland biomes. In some instances, such as in North America, longitudinal zones dominate and replace each other in an east-west direction across the mid-continent (i.e., tallgrass prairie to shortgrass prairie). In other areas, such as Eurasia, latitudinal zonation is more prominent, with biomes changing in a north-south direction. Still other natural grasslands are a consequence of rainshadows on the lee sides of major mountain ranges or of high elevation, or of specialized droughty substrates (Woodward, 2008).

Soil/substrate/hydrology: Temperate grasslands are often found on soils that are highly fertile and productive, though large expanses of sandy soils may also occur. Soils are built from the combination of dense roots and the annual die-off of above ground vegetation. More living biomass exists below ground than above. The highly fertile soils are classified as mollisols (USDA Soil Taxonomy, also called chernozems) and are rich in humus in both the A and B horizons. The soils often contain loess material, rich in carbonates (Woodward, 2008).

Animals: Herbivorous mammals play an important role in regulating vegetation structure and composition in temperate grasslands. They may either be migratory ungulates, such as pronghorn or bison, that move in either small or large herds, or they are burrowing rodents, such as prairie dogs, that live in colonies. Insects are also key herbivores, with grasshoppers especially abundant. Animal diversity is relatively low, especially in comparison to the animals of some tropical grasslands (Woodward, 2008) (Fig. 1).

Geographic range: Temperate grasslands and shrublands occur in the middle latitudes (25–55°) of the northern and southern hemispheres. The largest expanses are found in North America (“prairies”) and Eurasia (“steppe”), with smaller but substantial areas in South America (“pampas”) and southern Africa (“veld”) (Woodward, 2008).

Boreal variant: Poleward of the temperate grassland are minor areas of Boreal Grassland and Shrubland, dominated by mesomorphic perennial grasses and forbs, with shrubs of varying dominance. Mosses and lichens play a larger role than in other grasslands. This type is associated with cold semi-arid to moist climates, with extended cold winters and short mild summers, and geographically occurs mixed with boreal forests and wetlands. The climate generally favors establishment of forest vegetation; thus, the absence of forest vegetation is a result of local conditions related to water regime, soil parameters (including thin, rocky sites),

Fig. 1 American bison (*Bison bison*) are large herbivores that shape Central North American grasslands, including at the Tallgrass Prairie Preserve in Oklahoma. Photo by Don Faber-Langendoen.

or disturbance regimes. There are lengthy periods of freezing temperatures with the coldest month isotherm of -3°C , and the growing season generally averaging <100 days, occasionally interrupted by nights of below-freezing temperatures. Snow may be present for extended periods (7–10 months) and soils are frozen in winter. Annual precipitation is 38–50 cm (15–20 in.). The northern and southern boundary of these boreal grasslands may be similar to that of boreal forest. This formation is found in the northern mid-latitude regions of North America and Eurasia, extending through much of the boreal region between 55° and 70°N latitude.

Biogeographic Distribution of Tropical, Temperate, and Mediterranean Grasslands

To show the grassland types and their distribution, two systems were integrated: the International Vegetation Classification (IVC) at the Division level to help characterize global and continental biome types (Faber-Langendoen et al., 2014), and Terrestrial Ecoregions of the World (TEOW) (Olson et al., 2001; Dinerstein et al., 2017) to show their distribution. By integrating these two systems, we generated a systematic, spatially-explicit framework that broadly accounts for grassland biodiversity (as continental biome or IVC division types) and the spatial ecoregion within which these grassland types occur (Dixon et al., 2014).

In the IVC, a formation (akin to a global biome) represents combinations of dominant and diagnostic growth forms that reflect macroclimatic factors such as altitude, seasonality, substrates, and hydrologic conditions. Nested within each formation are a set of divisions (akin to continental biomes), which describe broadly uniform growth forms and a broad set of diagnostic plant species at large biogeographical scales, reflecting continental gradients in ecological factors (Faber-Langendoen et al., 2014). At both the formation and division levels, the ecological and vegetation types include a range of grassland and related shrubland types. For example, the IVC division Patagonian Grassland and Shrubland (Table 1) includes reference to both grassland and shrubland because they strongly overlap in floristic composition, growth forms, and biogeography. However, within the hierarchy, a lower level plant community distinction may eventually be made between the grassland and shrub types.

The IVC defines 51 distinct tropical, mediterranean, and temperate grassland division types, creating a new global biogeographical representation of earth's grassland types (Fig. 2). Divisions are mapped by ecoregion, for all ecoregions where they historically occupied at least 10% of the ecoregion (see Dixon et al., 2014 for details, including Appendix S2 for a list of all TEOW ecoregions where a grassland type occupied at least 10% of the given ecoregion). This map capitalizes on the use of both the IVC and TEOW to develop a platform for global grassland conservation policies. Furthermore, describing grasslands and their spatial distribution in this way provides decision makers with robust information on global grassland biodiversity patterns (Dixon et al., 2014).

The maps demonstrate how unique levels of biodiversity, particularly species biogeographic differentiation, emerge at the division level. For example, within the temperate grassland formation, there is little to no species overlap between the Eastern Eurasian Grassland and Shrubland division and the Great Plains Grassland & Shrubland division. At this division level, species attributes such as richness, abundance, and endemism may begin to be used, facilitating management and policy decisions. Development

Fig. 2 Diversity of continental-scale grassland types based on the division level of the International Vegetation Classification. From Dixon, A., Faber-Langendoen, D., Josse, C., Morrison, J. and Loucks, C.J. (2014). Distribution mapping of world grassland types. *Journal of Biogeography* 41, 2003–2019. and reproduced with permission from John Wiley and Sons.

of levels below division, such as that of macrogroup and group, would further enhance the application of the grassland types, because these levels are more comparable to types used by other widely used regional classifications (Dixon et al., 2014).

Other aspects of grassland processes may emerge at somewhat broader biogeographic scales. For example, Lehmann et al. (2014) found that although a common set of environmental drivers shape tropical savannas across the globe, there are important differences in how these drivers interact at the continental level. These differences include response of woody biomass to climate change, e.g., climate change could lead to increased woody biomass in Africa because the woody species that have evolved on that continent respond differently to fire-temperate interactions than do the species on other continents.

Biodiversity of Grasslands

Grasslands are notable for their contribution to biodiversity, both in terms of species diversity and the diversity of crop cultivars. The major cereal crops of the world are grasses, and their origins are in grasslands. The genetic diversity of wild stock continues to be a means for improving cereal and forage cultivars. Gibson (2009) noted that 40 of the world's 234 Centres of Plant Diversity (CPD) identified by the International Union for Conservation of Nature and Natural Resources (IUCN) and World Wildlife Fund-US occur in grasslands, with an additional 70 CPDs containing some grassland habitat. To qualify as a CPD, mainland areas must contain 1000 vascular plants with 10% endemism. Gibson also notes that perhaps the biologically richest grassland worldwide is that of the Agulhas Plain, part of the Cape Floristic Province of South Africa. This region, considered as one of the world's 25 biodiversity hot-spots for conservation contains a flora of 1751 species, including 23.6% regional endemics and 5.7% local endemic in a landscape of shrubland, savannah, and fynbos. Other regions, particularly in the northern hemisphere, are of more recent origin and do not contain the same levels of diversity.

From a very different angle, Veldman et al. (2015) approach the biodiversity of grasslands from an "old-growth" perspective; namely, that grasslands, despite their apparent ephemeral above ground structure, are ancient ecosystems with high herbaceous species richness, high endemism and unique species composition (as reflected in our division/continental biome types).

Grassland Productivity, Ecosystem Services and Climate Change

Grasslands have both intrinsic (non-use) and economic (use) values. Intrinsic values focus on the aesthetic, cultural, and ecological values that grasslands provide, irrespective of any direct benefit to humans. Economic values include grazing livestock, harvesting native or cultivated plants, hunting wildlife, recreational activities (e.g., hiking, bird watching, photography), educational activities, erosion control, water quality control, and research activities. Some of these economic values may degrade or even destroy the grasslands, and for that reason, there has been growing interest in pricing ecosystem functions, goods, and services based on the persistence of native grasslands. We consider several here: carbon storage, agriculture and biofuels.

Carbon Storage and Agriculture

Grasslands are an important contributor to global carbon storage because of the high levels of carbon accrual and sequestration below ground in the soil. According to Gibson (2009), up to 90% of grassland biomass is below ground and levels of soil carbon are higher in grasslands than in forests, agroecosystems, or other ecosystems. Temperate grasslands in particular have high storage rates, because decomposition rates are generally low and soil organic matter has accumulated over thousands of years. By contrast, tropical grasslands have high above ground production because of the warmer temperatures, but below-ground storage is low. In both cases, grasslands are a potentially important sink for carbon in the terrestrial biosphere. For these reasons, there is concern that their role as a carbon sink could be lost in response to global climate change.

The effects of climate change on carbon storage may be small relative to the large impacts cause by conversion of grasslands for agricultural production. Many regions of the world have lost substantial portions of the grasslands (e.g., as much as 98% in North American tallgrass prairie), and many agricultural uses have led to soil erosion and loss of organic matter. Improved agricultural methods could minimize loss of soil organic matter, but for degraded soils, recovery is slow, taking 50 or more years. Gibson (2009) notes that other causes of carbon loss from grasslands include fire, grazing, and exotic species. Burning tropical grasslands, for example, releases carbon to the atmosphere, and contributes up to 42% of gross CO₂ to global emissions.

Agricultural Grazing

Natural grasslands have a long history of use by human, including production of domestic livestock principally mammalian herbivores: cattle, sheep, goats, horses, water buffalo, and camels. According to Gibson (2009), the densities of livestock in grasslands range from 1 to 100 head/km⁻², with the highest densities in the world in the Middle East, Asia, and Australia. Densities may still be on the rise, with the potential for overgrazing and a degraded grassland range.

Biofuels

In the quest of sustainable energy sources, researchers have turned to perennial grasses and native grasslands. Mixtures of native grassland perennials, referred to as low-input high-diversity (LIHD) biofuels, were shown to exhibit bioenergy yields 238% greater than monocultures (Gibson, 2009). Moreover, these LIHDs are particularly valuable because they sequester more CO₂ in the soil and roots than released during conventional biofuel production. But there are tradeoffs because the ecological traits of a grass species bred for biofuel production are also known to contribute to invasiveness, prompting concerns regarding the ecological risks involved in introducing and planting them (Palik et al., 2016). Many grassland biofuel species are invasive outside their native range.

Grasslands in Crisis—Conservation Strategies

Grasslands have historically been subject to a wide variety of human uses, including conversion to crops or other types of farming. Temperate grasslands are considered among the most threatened biomes worldwide (Hoekstra et al., 2005), but increasing pressures on tropical grasslands from agricultural expansion, heavy grazing and continued population growth may soon make them equally threatened. These threats challenge governments, business, and civil society to develop policies that address conversion pressures on global grassland ecosystems and seek to balance development with conservation. However, decision makers currently lack a framework to monitor global grassland biodiversity for both biological uniqueness and total historic distribution. One promising initiative is the International Union for the Conservation of Nature's (IUCN) proposed Red List of Ecosystems, where the likelihood that an ecosystem will persist into the future is assessed (Keith et al., 2013). Another is the increased focus on national reporting of progress toward "Aichi Targets" under the United Nations Convention on Biodiversity (CBD). Aichi Target 11 states that "By 2020, at least 17 percent of terrestrial and inland water areas... especially areas of particular importance for biodiversity and ecosystem services, are conserved through effectively and equitably managed, ecologically representative and well-connected systems of protected areas and other effective area-based conservation measures and integrated into the wider landscape and seascape." Tools are being developed to measuring progress in meeting these targets based on a suit of indicators (Han et al., 2017), which can help conservationists and policy makers assess priorities for grassland conservation.

Acknowledgments

This review of grasslands would not have been possible without the legwork of the Hierarchy Revisions Working Group that completed the Faber-Langendoen et al. (2016) publication. In particular, for the grasslands work summarized here, I thank Carmen Josse and Todd Keeler-Wolf. This work was also informed by the popular but comprehensive work of Susan Woodward's (2008) Grassland Biomes book and by David Gibson's (2009) book on grasslands. Finally, Adam Dixon provided the lead on linking the International Vegetation Classification with the Ecoregions of the World map, and I thank him for the high-quality maps that became part of our Dixon et al. (2014) paper.

Glossary

Bunchgrass Perennial grass species that usually grow as singular plants in clumps, tufts, hummocks, or bunches, rather than forming a sod or lawn.

Cool Season Grass Grass species that reach maximum growth and flower later from spring to early summer using a C_3 photosynthetic pathway.

Mixedgrass Prairie Grassland communities with plant species that tend to grow above waist height, thus they are middling in height between the shortgrass prairie to the west and the tallgrass prairie to the east, and hence the name mixed grass prairie.

Semi-Desert Grassland Grassland communities, often of irregular or sparse vegetative cover, of warm deserts that are dominated by bunchgrasses and succulent plants.

Shortgrass Prairie Grassland communities with plant species that tend to grow well below waist height, and hence the name shortgrass prairie.

Sod-forming Grass Grass species that spread by means of a specialized structure known as a rhizome, which is a modified root. When the rhizomes grow into dense mats, they are referred to as sod forming.

Tallgrass Prairie Grassland communities with plant species that tend to grow well above waist height, and hence the name tallgrass prairie.

Warm Season Grass Grass species that reach maximum growth and flower later from mid to late summer using a C_4 photosynthetic pathway (common to most plants) that enables plants to reduce moisture stress.

Nomenclature

International Vegetation Classification Provides a comprehensive multi-level structure to describe and classify the world's vegetation. The classification is based on vegetation and ecological criteria, including vegetation growth forms and structure, plant species, and ecological characteristics such as site, disturbance, bioclimate, and biogeography.

IVC Group A relatively narrow set of diagnostic plant species (including dominants and codominants), broadly similar composition, and diagnostic growth forms that reflect regional mesoclimate, geology, substrates, hydrology, and disturbance regimes.

NatureServe Terrestrial Ecological System A terrestrial ecological system is defined as a group of plant community types that tend to co-occur within landscapes with similar ecological processes, substrates, and/or environmental gradients.

Abstract

Grasslands dominate the central regional landscape of the North America, extending from the Canadian prairies south across the Chihuahuan Desert. We describe this grassland diversity, discussing common forms of ecological classification, and highlight the International Vegetation Classification. We then report on a series of analyses and a Landscape Conservation Design for temperate grassland conservation. We targeted 12 major grassland ecosystem types that occur across this region.

Component analyses included: (a) documenting long-term trends in extent by grassland type, (b) assessing landscape intactness among grassland areas, and (c) identifying Grassland Potential Conservation Areas to advance grassland conservation. Most severe declines in grassland extent have occurred in tallgrass prairie types, followed by mixed-grass, shortgrass, and semi-desert grasslands. Similar trends by type were documented for landscape intactness and connectivity. A total of 177 Grassland Potential Conservation Areas (GPCAs) were identified to represent grassland type diversity in areas least likely to conflict with other land uses. Within identified GPCAs, type-specific representation varied from a low of just 1% of historic extent for Texas Blackland Tallgrass Prairie to a high of 27% for Western Great Plains Sand Prairie. Combined across all 12 grassland types, 15% of historic extent is represented.

Introduction

The North American grassland biome occupies a large expanse of the continental interior. The types of grassland are typically differentiated based on the height of the predominant species (tallgrass, mixed or mid grass and shortgrass) or the prevailing climate (desert grassland). The region is also known for a gently rolling landscape that is punctuated by rugged badlands. The words grassland or prairie, however, evoke images in the popular imagination; herds of massive American bison (*Bison bison*) grazing beneath dazzling blue skies, nomadic Native American peoples encamped along clear streams, and a west bound Prairie Schooner navigating the Great Ocean of grass. But this is an ancient landscape. The earliest grass fossils date from roughly 19 million years before the present. At that time, the vegetation was a mosaic of savannah vegetation and open grassland.

Humans have influenced the structure of the grasslands since their arrival 15,000 years ago. But the changes in human population density, technology, and land use in the 19th century, initiated decades of profound changes to the grasslands. Because of rich and abundant soils, grassland conversion for agricultural purposes has been an ongoing process for centuries. Arguably, the pace of conversion was slow following arrival of Euro-American settlers seeking the independence of an unfettered agrarian life. Their cultivation of western lands, however, followed practices that were appropriate in the humid east, but unsuitable in the semi-arid Great Plains. The pace of grassland loss accelerated with the invention of the steel plow. First introduced by John Lane in 1833 and later modified and manufactured by John Deere, thousands of plows pulled by oxen began to break the prairie soil. As the steel blade cut the dense, intertwined network of roots in the prairie sod, the sound was likened to that of a zipper. Those soils have long since eroded away. The arrival of railroads also facilitated agricultural intensification by providing rapid transport of commodities to distant markets, thus increasing the strain on native grasslands. Although some of these lands were retired from crop production following the Dust Bowl of the 1930s, more recent trends in agricultural intensification of the Chihuahuan Desert (Pool et al., 2014), biofuel production (Wright and Wimberly, 2013), and energy development (Pruett et al., 2009; Fargione et al., 2012), have introduced pockets of rapid change across the region (Drummond et al., 2012).

In this article, we discuss the following topics: how do ecologists distinguish and classify grassland vegetation? How can the past distribution of grasslands be mapped and compared with the current extent of grassland vegetation? Do “intact” remnants of grassland vegetation exist and how are place-based conservation priorities set?

Classifying the Grassland Biome

Classifying vegetation (defined here as “plant cover, including both floristic composition and vegetation structure, documented at a specific location and time, under specified ecological conditions, and preferably described at an optimal time during the growing season”) requires careful consideration of the species present and their proportions relative to one another and the physical environment that they inhabit. The species composition and grassland vegetation in the Great Plains reflects three major environmental gradients. The first is a marked increase of average annual and monthly temperatures from north to south. The second is an increase in annual precipitation from west to east, the product of both a rain shadow, created by mountains to the west, and the location of much of the region near the center of the continent. And finally, elevation which increases from east-to-west because of the Rocky Mountain uplift. When developing descriptions of vegetation, ecologists include adjectives that reflect these environmental factors.

Ecologists also incorporate species traits to distinguish units of vegetation. All plants exhibit adaptations to regional climatic factors. In the case of grassland plants, drought and high sunlight can affect the efficiency of photosynthesis. Thus, range managers and ecologists speak of cool season grasses as adapted to cool-moist conditions and reach maximum growth and flower during the spring and early summer. Warm season grasses are those that are adapted to hot-dry conditions and reach both maximum growth and flower later from mid to late summer. Underlying these distinctions is a difference in the mode of photosynthesis utilized. The C_3 photosynthetic pathway is typical of cool season grass species (Ehleringer and Cerling, 2002). But under hot and dry condition, plants experience water loss and hot temperatures that cause a decline in photosynthetic efficiency. The adaptations of C_4 photosynthesis alleviates much of this stress.

Grasses can also be categorized as rhizomatous grasses (or sodding forming) versus bunchgrasses. Rhizomatous grasses spread through the soil by a specialized structure known as a rhizome, essentially a modified root. When the rhizomes grow into dense mats, they are referred to as sod forming (Weaver, 1954). Euro-American settlers learned that the dense prairie sod could be cut into blocks and used like bricks to construct house, known as “soddies” (Thornthwaite, 1941). Bunch grasses grow in clumps, producing space between individuals of the same species.

Table 1 International Vegetation Classification Hierarchy, example from Temperate North America including the number of natural types in the conterminous United States as of 2019.

Level no.	Level name	Defining characteristics	No. types	Example
1	Class	Life form Physiognomy	6	Grassland and shrubland
2	Subclass	Global physiognomy	11	Temperate and Boreal grassland and shrubland
3	Formation	Global physiognomy	24	Temperate grassland and shrubland
4	Division	Continental floristics	51	Great plains grassland and shrubland
5	Macrogroup	Subcontinental floristics	121	Great plains tallgrass prairie
6	Group	Regional floristics	319	<i>Northern Great Plains Tallgrass Prairie</i> <i>Schizachyrium scoparium—Bouteloua curtipendula</i>
7	Alliance	Subregional floristics	1201	Northern Grassland <i>Schizachyrium scoparium—Bouteloua curtipendula—Hesperostipa spartea—(Pascopyrum smithii) Grassland</i>
8	Association	Local floristics	5794	

The International Vegetation Classification (IVC) provides a hierarchical framework for the classification and description of vegetation types (Faber-Langendoen et al., 2014). The IVC draws upon bioclimatic, biogeographic, and soils data to develop coherent classification units at each scale. It is important to emphasize that an IVC unit represents existing vegetation (i.e., a suite of species that are present currently at a given location), and not potential natural vegetation (i.e., the species that might be present in a location in the absence of human action) (Zerbe, 1998). The IVC is organized into eight levels (Table 1). The three upper levels (Formation Class, Formation subclass, Formation) segregates vegetation into units based upon the dominant and diagnostic growth forms as a reflection of the macroclimatic as modified by altitude, seasonality of precipitation, substrates, and hydrologic conditions. These levels are too generalized for our needs here but note that the North American Temperate Grasslands fall within the Shrub and Herb Formation Class, the Temperate and Boreal Grassland and Shrubland Formations Subclass and the Temperate Grassland and Shrubland Formation. Vegetation often referred to as “shrub steppe” such as big sagebrush (*Artemisia tridentata*)-dominated steppe in Montana, is classified in the “Cool Semi-Desert Scrub and Grassland” Formation, the “Western North American Cool Semi-Desert Scrub and Grassland” Division, and the “Great Basin-Intermountain Tall Sagebrush Steppe & Shrubland” Macrogroup. Shrub steppe is intermediate between more dense shrublands and temperate grasslands. They are widespread across the western Great Plains and intermountain region, but are not treated here with the predominant temperate grasslands.

Our discussion of the North American Temperate Grasslands will be center on the “Group” in the mid-level (Division, Macrogroup, and Group) of the IVC, defined as a “relatively narrow set of diagnostic plant species (including dominants and codominants), broadly similar in composition, and diagnostic growth forms that reflect regional mesoclimate, geology, substrates, hydrology, and disturbance regimes.” Thus, each unit in the mid-level is defined based on four criteria: characteristic taxa, physiognomy, ecology, and biogeography. Naming conventions for all categories in the IVC require that both a scientific and a common name be provided to facilitate utility among broad groups of users. For example, the scientific name *Andropogon gerardii—Heterostipa spartea—Muhlenbergia richardsonis* Grassland Group corresponds with the common name Northern Mesic Tallgrass Prairie. Group common names will be used in this article. The lower levels of the classification (e.g., alliance and the association) will not be discussed here.

The North American Temperate Grasslands fall within the Central North American Grassland and Shrubland Division and are distributed among four macrogroups: Great Plains Mixedgrass and Fescue Prairie, Central Lowlands Tallgrass Prairie, Great Plains Sand Grassland and Shrubland, and Western Great Plains Shortgrass Prairie. Of the several hundred Groups in the IVC, 24 occur in the Great Plains, nine of which are grasslands. The remaining 15 Groups represent wetland, shrubland, and riparian vegetation. Several more semi-desert grassland types occur in the Chihuahuan Desert in temperate to subtropical latitudes of the southwest United States and adjacent Mexico. The descriptions of the grassland Groups that follow will begin at the northern extent of this biome and proceed southward, thus highlighting changes in species composition as related to changing temperatures.

The Great Plains Mixedgrass & Fescue Prairie macrogroup consists of four units: the Central Great Plains Mixedgrass Prairie, Northern Great Plains Dry Mixedgrass Prairie, Northern Great Plains Mesic Mixedgrass Prairie, and Northern Great Plains Rough Fescue Prairie. The distribution of these grasslands has been impacted either directly or indirectly by glacial history. Over a time-span of 2.5 million to 11,000 years ago, the region was subject to four major glacial episodes which forced plant and animal species south and obliterated or restructured soils. Since the last glaciation, soil development on gently rolling to flat terrain and influenced by the cool climate have developed into deep silty loam Mollisols, which are some of the most agriculturally productive soils on earth. As a result, much of the natural vegetation has been replaced by row crop agriculture.

Because temperatures in this region are cool, the predominate grasses are cool season species. Warm season grass species are present, particularly in the southern portion of the region, but they are low in abundance. The term mixedgrass refers to the stature of the predominant grasses; midway or a mix in height between those of the tallgrass and shortgrass prairies.

The Northern Great Plains Rough Fescue Prairie is reported only from the western Canadian provinces of Alberta, Manitoba, and Saskatchewan. Grasslands within this Group are dominated by Hall’s Fescue (*Festuca hallii*) with Timber Oatgrass (*Danthonia*

intermedia), Thick-spike Wheatgrass (*Elymus lanceolatus*), Needlegrass (*Hesperostipa* spp.), Ricegrass (*Achnatherum* spp.) as codominants. Hall's Fescue is limited to very high latitudes in North America and high elevations in the United States.

The Northern Great Plains Dry Mixedgrass Prairie is reported from Alberta, Saskatchewan, Montana, North Dakota, and Wyoming. The vegetation is characterized shortbristle needle and thread (*Hesperostipa curtipendula*), thickspike wheatgrass (*Elymus lanceolatus*), bluebunch wheatgrass (*Pseudoroegneria spicata*), western wheatgrass (*Pascopyrum smithii*), needle and thread (*Hesperostipa comata*), Idaho fescue (*Festuca idahoensis*), and sun sedge (*Carex inops* ssp. *heliophila*). Western wheatgrass and thickspike wheatgrass are rhizomatous species, while the others are considered bunchgrasses.

The Northern Great Plains Mesic Mixedgrass Prairie occurs from Alberta, Saskatchewan, and Manitoba, south to Nebraska, and Wyoming. It typically occupies narrow valleys, stream terraces, and rolling uplands and mesic slopes. The soils are loams with well-developed profiles. Although it overlaps geographically with the Northern Great Plains Dry Mixedgrass Prairie, the two differ on the basis of moisture regimes and the secondary species present. The number of warm season grass species increases in this Group, such as big bluestem (*Andropogon gerardii*), little bluestem (*Schizachyrium scoparium*), and Indiangrass (*Sorghastrum nutans*). Green needlegrass (*Nassella viridula*) and western wheatgrass, both cool season species, are also common components of this Group.

The Central Great Plains Mixedgrass Prairie Group covers the widest geographic extent of the Groups considered here, extending from New Mexico, Oklahoma and Texas, north to southern Nebraska. Warm season grasses predominate on all sites. In addition to big bluestem, little bluestem, and Indiangrass, blue grama (*Bouteloua gracilis*), hairy grama (*Bouteloua hirsuta*), and sideoats grama (*Bouteloua curtipendula*) are common co-dominant species. The area is a mosaic of grasslands interspersed with woody vegetation. On sandy soils, sandsage (*Artemisia filifolia*) shrublands are common and less frequently, shiner oak (*Quercus havardii*) woodlands. The mixedgrass prairie is intensively utilized for the cultivation of winter wheat, cotton, milo, and livestock. Due to suppression of fire, overgrazing, and land abandonment, eastern red cedar (*Juniperus virginiana*) had replaced grassland cover in overgrazed pastures and abandoned fields and represents an economic and ecologic threat in many areas.

Central Lowlands Tallgrass Prairie macrogroup consists of four Groups; the Northern Tallgrass Prairie, Central Tallgrass Prairie, Southern Tallgrass Prairie, and Blackland and Coastal Tallgrass Prairie. These grasslands tend to receive more rainfall and experience greater humidity relative to the western grasslands. They occur on a wide variety of soils, ranging from deep, well-formed mollisols and shallow soils and outcrops over limestone. Big and little bluestem and Indiangrass are predominant species in these Groups. On dry, shallow soils, hairy and sideoats grama are co-dominants. In lowland prairies, switchgrass (*Panicum virgatum*) is a dominant species, as was prairie cordgrass (*Spartina pectinata*), but its abundance has been greatly reduced in areas by cattle grazing.

The Northern Tallgrass Prairie Group extends from Manitoba, Ontario and Minnesota south through Nebraska, South and North Dakota, and east into Iowa and northern Missouri. Like the Northern Mixedgrass Prairie Groups described above, vegetation distribution and patterns were affected by glacial cycles. Although the warm season grasses big and little bluestems, and sideoats grama are predominant grasses, several cool season species such as porcupine grass and western wheatgrass also characterize these grasslands.

The Central Tallgrass Prairie and Southern Tallgrass Prairie Groups share many features. Of the two, the Central Tallgrass Prairie covers the greatest geographic area, ranging from the Great Plains into the Prairie Peninsula of Ohio, Indiana, and Illinois (Transeau, 1935). The Central Tallgrass Prairie of Kansas, Nebraska, and South Dakota is within the region considered here. Southern Tallgrass Prairie occupies a smaller range that includes Kansas, Oklahoma, and Texas, with extension into Arkansas and Missouri. Unlike the Northern Tallgrass and portions of the Central Tallgrass, the Southern Tallgrass Prairie was not directly affected by glaciation.

Of the Blackland and Coastal Tallgrass Prairie Group, only the Blackland Prairie occurs in the region under consideration. The soils have developed over limestone and tend to have high pH. Both Alfisols and Vertisols are present with the inclusion of mima mounds. Little bluestem and Indiangrass are frequently the dominant species. Silveus' dropseed (*Sporobolus silveanus*) is prevalent in Blackland Prairies on Alfisols. Mead's sedge (*Carex meadii*) and prairie bishop (*Bifora americana*) are also characteristic species.

The Great Plains Sand Grassland & Shrubland macrogroup consists of the Great Plains Sand Grassland and the Great Plains Sand Shrubland. Soils tend to be nutrient poor, weakly developed, and well drained. Vegetation is sparse and a mix of grass and forb species on large sand dunes. Plant species in this Group must be adapted to these rather extreme conditions. Although the Great Plains Sand Grasslands occur throughout the region (Manitoba and Saskatchewan, south through the Montana and the Dakotas to Oklahoma and Texas), it interdigitates or is locally restricted within the grassland Groups described above. Sand bluestem (*Andropogon hallii*) is a predominant species, with prairie sand reed (*Calamovilfa longifolia*) as a co-dominant in northern locations, and giant sand reed (*Calamovilfa gigantea*) as a co-dominant in the south. The Nebraska Sandhills, a mosaic of wetland and grassland vegetation, is the best-known region with this Group (Loope and Swinehart, 2000).

The Great Plains Shortgrass Prairie is the only Group in the Western Great Plains Shortgrass Macrogroup. The Shortgrass Prairie intergrades with foothill vegetation of the Rocky Mountains in Colorado and New Mexico and extends east to the Colorado border, the Oklahoma Panhandle, and southwest Texas. Soils formed over the Ogallala outwash, and Permian period sandstones, with scattered outcroppings of earlier Paleozoic Era formations. The soils range from shallow and rocky to deep Mollisols. The predominant grasses and forbs are of short stature relative to species of the eastern grasslands, hence the name shortgrass. The iconic species of the shortgrass prairie are blue grama and buffalograss (*Bouteloua dactyloides*). The occurrence and abundance of these two species varies with soil type. On sites with shallow soils, side oats grama (*Bouteloua curtipendula*) and hairy grama (*Bouteloua hirsuta*) are codominant or dominant species. Much of the shortgrass prairie has been converted to the production of winter wheat, which is irrigated, or grazed by livestock.

The shortgrass prairie region is associated with one of the greatest environmental disasters to strike the United States, the Dust Bowl. A combination of drought and inappropriate land use practices resulted in the mobilization of soil by high winds, which in

one instance carried the dust to the Halls of Congress and into the Atlantic Ocean (McLeman et al., 2014). In the years following the disaster, ecologists documented an increased in geographic extent of the shortgrass prairie. In fact, a challenge for modern ecologists is determining which vegetation types are an expression of human mediated changes and which represent species assemblages in the absence of human influence.

Semidesert grasslands fall within the North American Warm Desert Scrub & Grassland Division, and Chihuahuan Semi-Desert Grassland Macrogroup. These grasslands may include sparsely vegetated patches as well as succulent shrubs or scattered small trees; all occurring along a transition to desert scrub or subtropical thornscrub. Some variation among four IVC Groups are reflective of grassland composition along elevation (from lower montane to foothill elevations) or by soils, with some types more strongly associated with sands, loams, and gypsum. Plant species such as bullgrasses (e.g., *Muhlenbergia emersleyi* and *Muhlenbergia setifolia*), New Mexico Feathergrass (*Hesperostipa neomexicana*), black grama (*Bouteloua eriopoda*), sotal (*Dasyllirion* spp.), side-oats grama (*Bouteloua curtipendula*), mesa dropseed (*Sporobolus flexuosus*), hairy crinklemat (*Tiquilia hispida*), Torrey yucca (*Yucca torreyi*), and tobosa grass (*Pleuraphis mutica*) variously characterize these IVC Groups.

Conservation Status and Trends

To determine the changing extent of grasslands in the Great Plains and Chihuahuan Desert, Comer et al. (2018) employed spatial technologies to compare distributions of targeted grasslands. They used spatial data layers consisting of a “biophysical setting” layer (potential/historical distribution) and “existing vegetation type” layer (current distribution) developed by LANDFIRE. That effort used inductive modeling with satellite imagery, climate, landform, and soil data (Rollins, 2009) to map the distribution for each major grassland type at spatial resolutions of approximately 5-ha minimum map unit. These maps use the NatureServe terrestrial ecological system classification (Comer et al., 2003), that align closely with either the Group or Alliance levels of the IVC hierarchy described above. From the map of potential or historic distribution of grassland ecological systems, 12 that exceeded 8000 km² in extent were selected for further analysis (Fig. 1). Of these, the Northwest Great Plains Mixed-grass Prairie had the greatest historical extent (~630,000 km²) and the Chihuahuan Sandy Plains Semi-Desert Grassland had the lowest (8100 km²) (Table 1).

Next, Comer et al. (2018) determined long-term change in extent by comparing the mapped distribution of grasslands (circa 2003) against the potential or historical extent from the previous analysis (Table 2). Direct conversion of grasslands for agriculture explained much of the change in areal extent for most types. Three types experienced a loss of greater than 90%: Texas Blackland Prairie (98%), Northern Tallgrass Prairie (96%), Central Tallgrass prairies (92%). These grasslands occur on productive soils in areas with significant summer rainfall, which enhances agricultural productivity. Based upon the “historic long-term trends in extent” criterion of the International Union for Conservation of Nature (IUCN) Red List Ecosystems (Keith et al., 2013), three grassland types would be considered Critically Endangered, four types Endangered, and three types Vulnerable (Table 2). If the 12 types are considered collectively, the loss would total 62% and qualify as Vulnerable.

Grassland Landscape Condition

Land conversion and subsequent land protection tell only part of the story of trends in temperate grassland biodiversity. A common factor in landscape design for biodiversity conservation is documentation of the relative condition or intactness, and key ecological processes such as connectivity, in any given area in order to inform conservation action (Groves, 2003). High condition or intact vegetation retains expected composition, structure, and dynamic process characteristics of sites that have not been altered by prior human land uses (Parrish et al., 2003). Substantial environmental degradation—due to wildfire suppression, soil compaction, overgrazing, and climate change—or alteration of biotic composition (i.e., invasive species introductions, landscape fragmentation and inhibition of dispersal by native species) and processes (i.e., wildfire suppression) have had substantial (albeit varying) impact on each grassland type (Samson et al., 2004).

Fragmentation of natural habitat by human activities can be mapped and used to identify intact core areas. Hak and Comer (2017) designed the NatureServe landscape condition model to calculate an index of relative intactness for the vegetation. The model integrates data layers representing roads, land uses, and maps of altered vegetation. The result is a grid layer of landscape condition with values falling between 0.0 and 1.0, where values close to 1.0 imply relatively little ecological impact from surrounding land use. The product is a wall-to-wall grid surface of landscape condition values falling between 0.0 and 1.0 (Fig. 2). For North American grasslands, it is clear that large proportions occur in some of the most intensively converted and fragmented landscapes. But one can also see that in western and drier portions of the region, more extensive and contiguous grassland areas remain.

Landscape Conservation Design

The United Nations Convention on Biodiversity (CBD), held in Nagoya, Aichi Prefecture, Japan in 2010, set five strategic goals consisting of 20 biodiversity targets, known collectively as the Aichi Targets. Strategy C strives to “improve the status of biodiversity by

Fig. 1 Potential or approximate historical location and extent of 12 major grassland types across the central interior of North America.

Table 2 Long-term trends in extent and at-risk status of 12 major grassland types.

Major temperate grassland type	Historical extent estimate (km ²)	Current extent estimate I (km ²)	Percent loss to conversion
Texas Blackland Tallgrass Prairie	41,400	670	98
Northern Tallgrass Prairie	157,200	6500	96
Central Tallgrass Prairie	242,000	20,100	92
Northern Great Plains Fescue Mixedgrass Prairie	137,000	18,000	87
Chihuahuan Sandy Plains Semi-Desert Grassland	8100	1600	80
Southeastern Great Plains Tallgrass Prairie	108,000	31,400	71
Central Mixedgrass Prairie	259,000	77,000	70
Western Great Plains Sand Prairie	107,300	38,000	65
Chihuahuan Loamy Plains Desert Grassland	38,300	14,400	62
Northwestern Great Plains Mixedgrass Prairie	620,900	307,500	50
Apacherian-Chihuahuan Semi-Desert Grassland and Steppe	249,400	152,200	39
Western Great Plains Shortgrass Prairie	259,000	188,000	27
Total	2,227,600	855,370	62

safeguarding ecosystems, species and genetic diversity,” and Target 11, a component of this strategy, states that “By 2020, at least 17 per cent of terrestrial and inland water, and 10 per cent of coastal and marine areas, especially areas of particular importance for biodiversity and ecosystem services, are conserved through effectively and equitably managed, ecologically representative and well connected systems of protected areas and other effective area-based conservation measures, and integrated into the wider landscapes and seascapes.” But how can we determine if this goal has been reached?

Grassland Priority Conservation Areas (GPCAs) is one vehicle to measure progress toward Target 11. Although GPCA analyses exist for grasslands in the Great Plains and Chihuahuan Desert (PCAP, 1998; Gauthier et al., 2003; Pool and Panjabi, 2011), all predate the CBD. Comer et al. (2018) completed a GPCA analysis to determine if the Target 11 goals might be achieved in grasslands. The analysis consisted of a grid of approximately 48,000 hexagons (each 100 km² in size). Although the area of the hexagon may seem large, it is a defensible choice given the geographic extent of the trinational region. A comparison was made of grassland extent and landscape intactness score. Hexagons with high areal grassland extent and high landscape intactness scored highest were then analyzed with consideration of existing managed/protected areas, land use intensity and connectivity, and the presence of at-risk species. The analysis produced 177 distinct GPCAs, with units in all 12 grassland types, which if conserved could achieve or surpass the Aichi Target 11 (Fig. 3 and Table 3).

The Western Great Plains Sand Prairie in the Nebraska Sandhills had the greatest modern extent within what was the historic range identified within GPCAs. At 27%, this far surpasses the 17% set in Target 11. Six additional major grassland types met or surpassed the 17% milestone of Aichi Target 11; Northwestern Great Plains Mixed-grass Prairie (21%), Chihuahuan Loamy Plains Desert Grassland (19%), Central Mixed-grass Prairie (18%), Southeastern Great Plains Tallgrass Prairie (18%), Western Great Plains Shortgrass Prairie (17%), and Apacherian-Chihuahuan Semi-Desert Grassland (17%). These types dominate the relatively dry-to-arid portions of the western Great Plains and extending throughout the Chihuahuan Desert. Of the tallgrass prairie ecological systems, only the Southeastern Great Plains Tallgrass Prairie achieved the 17% target. The majority of GPCAs in this grassland type were located on relatively shallow soils with extensive rock outcrops, areas with limited potential for cultivation, such as in the Flint Hills of Oklahoma and Kansas. GPCAs in the Chihuahuan Sandy Plains Semi-Desert Grassland were relatively small and fragmented areas and as a result, fell below the 17% milestone. Other grasslands that fell below the milestone were the Central Tallgrass Prairie (only 4% in GPCAs), Northern Great Plains Fescue Mixed-grass Prairie (4%), Northern Tallgrass Prairie (2%), and Texas Blackland Tallgrass Prairie (1%). When considered collectively, approximately 15% of all 12 major temperate grassland types occurred in identified GPCAs (Table 3). While just below the 17% Aichi Target 11 milestone, the selection of GPCAs still represents all major grassland types in areas most likely to support successful conservation.

Conclusions

Major grasslands of the Great Plains and adjacent Chihuahuan Desert span a vast region of high floristic diversity, and an array of temperature, humidity, and soil moisture regimes. The product is a variety of grassland vegetation types variously dominated by bunchgrasses or sod-forming species that are tall, medium, and short in stature. Dense and tall grasslands historically dominated the eastern, more humid margins of the Great Plains. In northern and central portions of the region, mixedgrass prairies remain dominant. To the southeast, shortgrass prairie dominates increasing warm and dry terrain, and semi-desert grassland becomes dominant further south extending across northern Mexico.

Given the severe impact of land conversion and fragmentation on most grassland types, we demonstrated a systematic approach, focusing on grassland type distributions, to advance toward global conservation targets such as Aichi Target 11 under the global Convention for biodiversity. Grassland Potential Conservation Areas can serve as one important focus for collaborative conservation action to build landscape resiliency in the face of accelerating environmental change.

Abstract

Much of the southeastern United States was covered by grassland vegetation (including savannas, woodlands, glades, and other open vegetation) prior to EuroAmerican settlement. This was particularly true for the southeastern Coastal Plain, where pine savanna/woodland covered roughly two-thirds of the landscape. However, grasslands were also prominent in other subregions of the Southeast. Collectively, these grasslands held a large proportion of the biodiversity of the Southeast, but they have suffered more serious declines than forests, estimated as around 90% for all types combined. This article summarizes major types of grassland in the region, factors responsible for creating and maintaining them, factors contributing to high levels of biodiversity in these communities, and prospects for the future.

Introduction

An old and widely repeated myth regarding the vegetation of the eastern United States is that a squirrel could travel from the Atlantic coast to the Mississippi River without ever once touching the ground, so dense were the forests (Matthiessen, 1959). Particularly in the southeastern United States, however, that squirrel would have had to take a very circuitous route. The southeastern United States, from the southern tip of Florida northward to Delaware, Maryland, and West Virginia, westward through the Ohio Valley, across the Mississippi and through Arkansas south of the Ozark Plateau, and including southeastern Oklahoma and eastern Texas, held large areas of prairies, savannas, open woodlands, glades, and other grasslands prior to EuroAmerican settlement (Noss, 2013; Fig. 1). Both historically and today, Florida contains more grassland vegetation than any other southeastern state.

Because converting grassland to crop fields is much easier than for forests, much of the grassland of the Southeast was lost before the first botanists or other naturalists in this region could describe them. These losses of grassland to agriculture escalated as the region became more settled, and they continue today. A considerable amount of grassland loss also was caused by fire exclusion. Both lightning (originally) and Native Americans were important ignition sources for fires in the region. Following an early Euro-American settlement period when fires actually increased in some parts of the Southeast due to frequent burning by settlers, the exclusion of fire caused many remnant grasslands to convert to forest. This fire exclusion was both deliberate and passive, the latter due to the effects of barriers such as agricultural fields and roads, which stopped the natural flow of fire across landscapes (Noss, 2018). Elimination of large grazing and browsing herbivores such as bison and elk facilitated replacement of grasslands by forest. Today the rampant urbanization of this region is eliminating most grasslands that are not secured within protected areas.

Despite the severe loss of native grassland ecosystems in the southeastern United States, those that remain hold an enormous portion of the region's biodiversity, especially endemic species (i.e., those found within a particular region but nowhere else in the world). Although most of the remnant grasslands exist only as small patches, some large grassland landscapes still remain, especially in the

Fig. 1 The southeastern United States, as defined in this article. The boundary is approximate. From *Forgotten Grasslands of the South*, by Reed F. Noss. Copyright © 2013 Island Press. Reproduced by permission of Island Press, Washington, D.C.

southeastern Coastal Plain. Moreover, active restoration can bring many former grasslands back. If second-growth forests on former grassland sites are logged or thinned, for example, and enough grass or other flammable material in the ground layer allows for controlled burning, grassland plants will often spring up from the seed bank where they've been buried for sometimes more than a century.

The purpose of this article is to summarize the major types of grasslands across the southeastern United States; briefly discuss the physical and ecological factors that created and maintained them; examine some reasons why these communities have such high and distinctive biodiversity; and consider what the future may hold for these communities in the face of rapidly changing climate and land use.

Types of Grasslands in the Southeastern United States

Many grassland ecologists favor an inclusive definition of grasslands, which takes into consideration the important role of the graminoid-dominated groundcover in the ecology of the community. Hence, grasslands may be treeless or treed, shrubby or not shrubby. For the purposes of this article, a grassland is any community in which the grass or graminoid layer, with its associated forbs, is the dominant layer in terms of plant cover, biomass, species richness, or at least two of these three. In the southeastern United States, natural community types that meet this definition include: prairies (which are treeless or nearly so); grassy balds (mountaintop prairies of the southern Appalachians); savannas and woodlands (typically with 10–80% tree canopy cover); barrens, glades, and outcrops (highly variable, often occurring in mosaic patterns and with considerable bare soil or rock); herbaceous wetlands; and canebrakes (dominated by species of *Arundinaria*, the American bamboo). As tree canopy cover approaches 80% or so, an ecosystem begins to behave ecologically more like a forest than a savanna/woodland, in the sense that the tree layer begins to shape the ecological processes, interactions, and dynamics of the system more than the ground (herbaceous) layer.

Table 1 lists some types of grasslands in the southeastern United States that fall into the general categories listed above. Examples of these community types are discussed in more detail below, though limited space precludes a detailed treatment.

Prairies

Prairies are ecological communities dominated by grasses and other herbaceous plants and with few or no trees. Some prairies are relatively shrubby, particularly if fire is excluded for a period of time. Trees also become more abundant with reduced fire frequency in many prairies, for example cabbage palms (*Sabal palmetto*) invading Florida dry prairie. Prairies occur on a variety of soils in the southeastern United States, including mollisols, clays, sands, and loams. Some southeastern prairies occur on deep mollisols or loams similar to those of the Central Tallgrass Prairie region, although more typically calcareous clays or sands are the primary soil types of southeastern prairies. Dominant grasses of southeastern prairies include little bluestems (*Schizachyrium* spp.), big bluestems (*Andropogon* spp.), three awns/wiregrasses (*Aristida*), and Indiangrasses (*Sorghastrum* spp.). There are also many species of prairie forbs, such as blazing-stars (*Liatris*), purple coneflowers (*Echinacea*), prairie clovers (*Dalea*), and prairie docks (*Silphium*).

Ecological systems are defined as “mid- to local-scale ecological units useful for standardized mapping and conservation assessments of habitat diversity and landscape conditions. Each ecological system type describes complexes of plant communities influenced by similar physical environments and dynamic ecological processes (like fire or flooding)” (<http://www.natureserve.org/conservation-tools/terrestrial-ecological-systems-united-states>). See also Noss (2013). Data from NatureServe Explorer.^b

^aCanebrake can exist as alternative stable state to forest in these bottomlands, especially on higher ground (“ridges”).

^b<http://explorer.natureserve.org/>.

These plant genera typically have greater species richness in the Southeast than in the more extensive prairies of the Great Plains, underscoring the antiquity of southeastern grasslands (Noss, 2013).

Major prairie regions of the southeastern United States include the Grand Prairie of the Mississippi Alluvial Plain of Arkansas; the Pennyroyal Karst Plain of Kentucky and Tennessee; the Coastal Prairie of Louisiana and Texas; the Black Belt Prairie (a type of blackland prairie) of Mississippi, Alabama, and a small portion of southern Tennessee; and the Florida Dry Prairie landscape of south-central Florida (Fig. 2). Most of these regions have lost the vast majority of their grasslands, on the order of 90–99.99% decline. Prairies and other grasslands in the unglaciated Southeast typically have higher plant species richness and a higher proportion of endemic species than prairies of the Great Plains, probably mostly because the more stable climate of the Southeast reduced extinction rates. However, geological and soil diversity are also high in the Southeast, species colonized the region from several other

Fig. 2 Florida dry prairie, Kissimmee Prairie Preserve State Park, Florida. This community is more accurately called a hyperseasonal subtropical grassland. Photo by Reed Noss.

regions, and disturbance was frequent enough to prevent competitive exclusion by dominant species—all of these factors likely contributed to high species richness.

At least three *Bison* species (going back to the Pleistocene) once roamed many southeastern prairies, most abundantly west of the Mississippi River. Animals and plants more typical of the western United States occur as disjunct populations in many southeastern grasslands. For example, in south-central Florida, the dry prairie and other grasslands contain the characteristically western bird species crested caracara (*Caracara cheriway*), burrowing owl (*Athene cunicularia*), and white-tailed kite (*Elanus leucurus*).

Grassy Balds

Grassy balds are essentially mountain-top prairies (Fig. 3), but their unique origins and histories suggest recognition as a separate class of communities. Communities of this general type occur in only a few places on Earth, most notably the southern

Fig. 3 A grassy bald, Roan Mountain, along the Tennessee-North Carolina border. This community is thought to have been maintained by a mixture of climatic factors and the activities of large herbivores. Photo by Reed Noss.

Appalachians (north to Virginia and West Virginia, and in the Cumberland Mountains along the Virginia-Kentucky line) at elevations of around 1500 m to nearly 1900 m, as well as in the Oregon (USA) Coast Range and the East Carpathian Mountains in the Czech Republic and Romania. The grassy balds of the southern Appalachians have cool temperatures most of the year and average annual precipitation approaching 250 cm. Dominant and characteristic plants include mountain oat-grass (*Danthonia compressa*), common hairgrass (*Avenella flexuosa*), bluejoint (*Calamagrostis canadensis* var. *canadensis*), mountain-cinquefoil (*Sibbaldia retusa*), Pennsylvania sedge (*Carex pensylvanica*), Gray's lily (*Lilium grayi*), mountain angelica (*Angelica triquinata*), Appalachian bluet (*Houstonia serpyllifolia*), and green alder (*Alnus crispa*).

Although fires occasionally occur on balds in drought years, fire is not a dominant factor in the origin and maintenance of these communities, given their generally moist and cool conditions. Indeed, the origin of these communities has been hotly debated for decades, with extreme exposure, fire, clearing by Native Americans or white settlers, grazing, and other factors suggested as most important. The currently best accepted explanation for the existence of grassy balds is the climate-herbivore hypothesis of [Weigl and Knowles \(2014\)](#). This hypothesis suggests that grassy tundra occupied these communities during the late Pleistocene, and megaherbivores such as mammoths, mastodons, horses, and ground sloths would migrate from the lowlands to graze and browse there during the summers. Nearby fossil sites document numerous species of Pleistocene megaherbivores in this region. When these herbivores were driven extinct, there were still native elk, deer, and bison in the area to maintain the grazing and browsing pressure. When these species were extirpated or greatly reduced by over-hunting by the late 18th century, the domestic livestock brought up the mountains by settlers to graze these balds in the summer continued the process of herbivory, but less effectively than the native megaherbivores. This likely explains, in part, the reduction in the size and number of grassy balds over time ([Weigl and Knowles 2014](#)).

Savannas and Woodlands

This category of communities is very diverse in the southeastern United States and constitutes the matrix or dominant vegetation over large portions of the region, particularly the Atlantic and Gulf Coastal Plains but also in some other subregions. Important community types included longleaf pine savannas across the Coastal Plain ([Fig. 4](#)), and savannas and woodlands with other pine species such as slash (*Pinus elliotii*), South Florida slash (*P. densa*), loblolly (*P. taeda*), pond (*P. serotina*), and shortleaf (*P. echinata*) pines. Savannas of shortleaf pine and bluestem grasses are major community types in the Ouachita Mountains of Arkansas and eastern Oklahoma, and shortleaf pine-post oak (*Quercus stellata*)-bluestem (*Andropogon gerardii*/*Schizachyrium scoparium*) savannas were characteristic of plateaus and ridges on the Cumberland Plateau of Tennessee and other parts of the Southeast.

Oak savannas and woodlands, including post oak, blackjack oak (*Q. marilandica*), and, especially in Kentucky, burr oak (*Q. macrocarpa*), were abundant, especially north and west of the Coastal Plain, for example in the Arkansas Valley ([Fig. 5](#)) and in Kentucky (Bluegrass Savanna and Woodland) and into the Midwest. These are among the most depleted of all ecosystem types in North America ([Noss et al., 1995](#)). Unusual savanna/woodland types in the Southeast include serpentine woodlands of the Piedmont and Blue Ridge provinces, the pine rockland communities of South Florida (primarily Miami Rock Ridge and Lower Keys),

Fig. 4 A longleaf pine savanna, also known as pine flatwoods. Forever Florida Preserve, near Holopaw, Florida. Pine savannas and woodlands of various types once covered approximately two-thirds of the southeastern Coastal Plain. Photo by Reed Noss.

where limestone pinnacles are commonly exposed on the surface, as well as dwarf cypress (dwarfed pond cypress, *Taxodium ascendens*) savannas in the Everglades and Big Cypress regions.

Fire was the primary factor that maintained most savannas and woodlands in the Southeast and prevented their conversion to closed forests. The frequency of cloud-to-ground lightning strikes is higher in the southeastern Coastal Plain than in any sizeable region of North America, and peaks in central Florida. In this region lightning was more important for igniting fires than Native Americans, presumably for millions of years and up to the time of EuroAmerican settlement (Noss, 2018). To the north and further from the coasts, lightning activity is lower, and at the time of EuroAmerican settlement most fires were probably lit by Native Americans.

Barrens, Glades, and Outcrops

This is one of the most heterogeneous categories of grasslands in the Southeast, further confused by the terms “barren” and “glade” being used in a variety of ways by different authors. As considered here, these communities range along a gradient from shallow-soil prairies (barrens), to sparsely vegetated communities with abundant exposed rock or bare soil (glades), to primarily rock with patches of grasses and other plants (outcrops, including flatrocks and domes). Given their generally harsh, primarily physically-controlled conditions, these communities are edaphic, meaning produced by the soil—of which there is often little. Examples of these communities include herbaceous serpentine barrens and woodlands, ranging from eastern Maryland and adjacent Pennsylvania to parts of the southern Appalachian Mountains and Piedmont in North Carolina and Georgia; limestone and dolomite glades and barrens from southern Ohio and Indiana, through Kentucky and Tennessee to Virginia and south to Alabama; sandstone glades and barrens on the Cumberland Plateau; shale barrens of the central and southern Appalachians, as well as the Ouachitas; granitic flatrock communities of the southern Piedmont, best developed east of Atlanta, Georgia (Fig. 6); and saline glades or barrens in Texas, Louisiana, and Arkansas. All of these communities, and others on more unusual substrates, have harsh physical or chemical conditions that are unfavorable to growth of woody plants. In some cases, such as some saline barrens and shale barrens on steep southwest-facing slopes, edaphic conditions are so extreme that fire does not appear necessary to maintain their grassland condition. In other cases, tree growth is impaired, but fire or other disturbances are necessary to prevent woody encroachment.

Given that barrens, glades, and outcrops are islands of distinct edaphic conditions in a sea of dissimilar geology and soils, one might expect that their isolation would provide ample opportunities for evolution of new species. And it often did. Southeastern glades and barrens are often packed with endemic species, some of which have their closest relatives a great distance away. An extreme example of high single-site endemism is the Ketona glades along the Little Cahaba River in central Alabama (Fig. 7). The shallow soil of this generally steep site is derived from Ketona dolomite, which has concentrations of magnesium high enough to be toxic to plants. Since the Ketona glades were discovered in 1992, nine new species and subspecies of endemic plants have been described from this site. All apparently evolved here in isolation. Throughout the southeastern United States, edaphic grasslands—often found only on very small sites—are of high priority for protection due to their unique biodiversity.

Fig. 6 A granitic flatrock community, Mt. Arabia, in the Georgia Piedmont east of Atlanta. The Precambrian granitic schists and gneisses support patches of grasses and other plants among abundant bare rock. Photo by Reed Noss.

Herbaceous Wetlands

Herbaceous wetlands generally lack tree cover and are dominated by grasses, sedges, rushes or other graminoid and herbaceous plants. Some of these communities are spatially extensive, such as freshwater, brackish, and salt marshes near the coast and the extensive sawgrass (*Cladium jamaicense*) sloughs and marl prairies of the Everglades, whereas others are usually small patch communities such as isolated bogs and fens. The hydroperiod—the annual duration of inundation—of a herbaceous wetland determines its ecology and species richness to a great extent. Longer hydroperiods usually result in lower species richness. For example, in the Florida Everglades, various marshes have hydroperiods of 6–12 months and typically fewer than 20 species on a site, whereas marl prairie (Fig. 8) has a hydroperiod of 2–4 months in most years and often more than 100 species on a site (Florida Natural Areas

Fig. 7 Ketona Dolomite Glades in Bibb County, Alabama. The dolomite bedrock contains extremely high levels of magnesium and supports only sparse plant cover over most of the area of exposed rock. Nine new species and subspecies of plants have been described, so far, on these glades since 1992. They exist nowhere else in the world. Photo by Reed Noss.

Fig. 8 A marl prairie in Big Cypress National Preserve, Florida. These prairies are usually inundated between 2 and 4 months of the year, during the summer wet season, so are not true wetlands. They have many more species of plants than the longer-hydroperiod marshes. Photo by Reed Noss.

Inventory, 2010). Some herbaceous wetlands, such as seepage slopes, are usually saturated but rarely inundated—i.e., there is little or no standing water. Herbaceous wetland communities are of many types and occur throughout the southeastern United States. Their inundated or saturated soil conditions, often in addition to frequent fire, prevent or reduce tree encroachment.

Canebrakes

Canebrakes often do not resemble grasslands, but they qualify as such because they are dominated by any of three species of cane or American bamboo, *Arundinaria*, which are in the grass family. They occur (or occurred) in seepage areas of pine savannas, in raised areas (“ridges”) of river floodplains, and a few other locations. On some sites fire alone may be adequate to maintain canebrakes, but in other cases, such as in bottomlands, a combination of disturbances appears to be required. Gagnon and Platt (2008) determined that canebrakes in floodplain/bottomland forest are maintained by fire or flood following a large canopy disturbance, such as a hurricane, tornado, or ice storm. The extinct passenger pigeon (*Ectopistes migratorius*) probably also helped maintain canebrakes (Noss, 2013). Their immense flocks roosted in bottomlands, especially in winter, and were reported to break apart tree canopies from their weight. They also produced abundant fertilizer, which favors cane. Passenger pigeons and large canebrakes disappeared together over the course of the 19th century; less than 1% of the historic canebrake area remains, with giant canebrakes (*A. gigantea*) especially depleted. Remnant canebrakes are distributed from the Ohio River Valley south to the Gulf of Mexico coast and central Florida.

Factors that Create and Maintain Southeastern Grasslands

Climate

One of the fundamental generalizations of biogeography is that grassland biomes occur along a climatic gradient between desert and forest (Coupland, 1991). This rule does not apply to grasslands of the southeastern United States. Whereas the Prairie Region of the Great Plains receives mostly between 30 and 76 cm of rain annually, the southeastern United States generally receives between 76 and 254 cm (https://nationalmap.gov/small_scale/printable/images/pdf/precip/pageprecip_us3.pdf)—quite enough to support dense forest virtually everywhere. Therefore, climate alone cannot explain the existence or distribution of southeastern grasslands. Nevertheless, historical periods of hot, dry weather appear to have promoted the eastward spread of grassland vegetation in the region (Transeau, 1935). Today, sites with hotter and drier microclimate, such as south- or southwest-facing slopes, often feature patches of grassland within a matrix of forest (Noss, 2013). Thus, modern climate does have an effect on grassland distribution in the Southeast, but mostly on a local scale. For an explanation of grassland occurrence across the region, we must look to other factors (below).

Fire

Fire is the paramount factor explaining the existence of grassland worldwide in regions with precipitation sufficient to support forest (Bond et al., 2005). Essentially, fire overrides the influence of climate in determining the distribution and abundance of vegetation types in regions such as the Southeast. Most types of grassland in the southeastern United States depend on at least occasional fire. Some grassland types—such as longleaf pine (*Pinus palustris*) savannas—require very frequent fire, on the order of every 1–3 years, to maintain their characteristic structure, composition, and species richness. Several independent lines of evidence suggest that fire has a long evolutionary history in this region: (1) charcoal in sediment layers of lake bottoms—although absence of charcoal does not indicate absence of fire; (2) fire-derived chemicals in ancient soils; (3) paleoclimate proxies such as sediment deposition patterns indicating dry/wet seasonal cycles, which favor frequent fire; (4) ancient fossils of plants found today in fiery habitats; (5) ancient fossils of vertebrates with morphologies adapted to savannas or other fire-maintained ecosystems; (6) high species endemism in fire-maintained ecosystems; and (7) high incidence of fire-adapted traits, such as thick bark, smoke-stimulated germination, underground organs for carbohydrate storage, and rapid resprouting after fire (Noss, 2018).

In fire-dependent grasslands, reduced frequency of fire results in invasion and increasing growth and dominance of woody plants and other plant species that lack traits adapted to frequent fire. Hardwood trees and shrubs, for example, increase in abundance and cover relative to grasses, long-needled pines, and other plants typical of savannas and other grasslands. The increased levels of fine fuels (e.g., grass thatch, fallen pine needles) and small woody stems after fire exclusion may lead to unusually intense conflagrations when fire finally returns. If a site continues to go without fire for many years, however, it may undergo what ecologists call a regime shift, transitioning to an alternative steady state such as hardwood forest, which is relatively non-flammable due to absence of flammable fine fuels. Only during a period of extreme drought may fire finally enter the community, but usually only some distance from an edge, and full recovery to the original frequent-fire community may be essentially impossible (Noss, 2018).

Substrate and Landform

As noted earlier under the discussion of barrens, glades, and outcrops, extreme or unusual geology or soils can favor grassland over woody vegetation. Edaphic grasslands may or may not require fire or other disturbances to prevent tree encroachment. For example, serpentine grasslands are found on ultramafic soils rich in magnesium, iron, and other metals such as nickel and chromium. These soils reduce effective moisture availability; have low amounts of the essential nutrients calcium, potassium, and phosphorus; high amounts of magnesium that further inhibits calcium uptake resulting in weak cell wall development; and have toxic effects on some plants (Tashakor et al., 2013). Many grasses and grassland forbs, though, thrive under these conditions of reduced competition. However, serpentine grasslands in the relatively wet southeastern United States cannot be maintained by soil properties alone—trees still invade, albeit more slowly than on less toxic soils. A combination of fire and harsh soils maintain southeastern serpentine grasslands.

In some cases, however, edaphic conditions can maintain grasslands in the Southeast even in the absence of fire. Many sandstone, limestone, and other glades have soils so thin that they are wet only for brief periods after rains but then dry completely (i.e., they are hydroxeric). This harsh condition in combination with the limited space available for tree roots assures relatively open-canopy conditions; whatever trees invade are usually killed during subsequent droughts. A type of shale barren, known as shale ridge bald, occurs primarily in Virginia on south- and southwest-facing slopes of mountains. The thin, shaly soils in combination with the hot, dry microclimate produced by maximum sun exposure prevents tree encroachment, apparently even in the absence of fire. As a final example, the saline barrens of Louisiana, southern Arkansas, and eastern Texas have such extreme alkali soils that woody plants cannot survive, except on small patches of more favorable soil, such as elevated mounds (“pimple mounds”) of wind-deposited soils.

Hydrology

Hydrology affects plant communities and limits tree encroachment and survival in many ways. In low-lying landscapes prone to seasonal flooding, a good way to assess the effects of hydrology is through consideration of hydroperiod, which as noted earlier is the period of time during a year that a site is inundated. Hydroperiod is usually expressed as a range because of interannual variability in precipitation. Different plant communities experience different hydroperiods, with those at lower elevations usually being inundated for longer periods. Long periods of inundation or tidal cycles exclude most tree species. In the southeastern United States, herbaceous wetlands with long hydroperiods are marshes of many types, which are often zoned along elevational gradients. A depression marsh, for example, may be inundated almost all year in its deepest, central zone, but only for a short period in the outermost zones. The mostly flat topography of Florida creates conditions for large floodplain marshes to be inundated from 120 to 350 days per year. Artificial drainage of marshes typically results in invasion by woody species (Florida Natural Areas Inventory, 2010). Most marshes in the Southeast also depend on frequent fire (which can burn through a marsh even while it is partially inundated) to prevent tree and shrub encroachment.

Herbaceous wetlands with short hydroperiods in the Southeast might be better considered grasslands than wetlands. A marl prairie (Fig. 8), with its short hydroperiod of 2–4 months, is at least as much upland as wetland. The so-called Florida dry prairie (Fig. 2) might be better called a hyperseasonal subtropical grassland, because its lower portions are usually inundated for a few weeks of the year. The interacting stresses of fire in the early rainy season (May–June) followed by inundation later in the rainy season effectively exclude trees from this ecosystem under natural conditions (Platt et al., 2006).

Some herbaceous wetlands in the Southeast have no true hydroperiod—they have saturated soils due to groundwater seepage but are rarely or never inundated. Prominent among these communities are seepage slopes (especially in Florida) and various types of bogs and fens across the region. Insectivorous plants such as pitcher plants, sundews, bladderworts, butterworts, and the Venus fly-trap (within its small native range in the Carolinas) are characteristic species in these communities.

Herbivores

Large herbivores may be second only to fire as a dominant ecological factor maintaining grassland vegetation worldwide. The hypothetical but highly probable role of grazing and browsing herbivores in maintaining the high-elevation grassy balds of the southern Appalachians was discussed earlier. To the west and north of this region, Pleistocene megaherbivores created and maintained a complex network of trails connecting salt licks where they gathered to consume the minerals, but often got mired in the mud and left their remains as fossils. These trails, called “Buffalo traces” by white settlers because they were used by bison at that time, extended beyond salt licks and allowed the herbivores to make seasonal migrations across a large region. The combination of grazing, browsing, and trampling by these animals created unique short-stature grassland conditions, in which endemic plants such as Short’s goldenrod (*Solidago shortii*), running buffalo-clover (*Trifolium reflexum*), and some other species apparently evolved. These plants have persisted in part in heavily grazed pastures adjacent to ancient buffalo traces (Noss, 2013).

The combination of fire and grazing may be particularly important to the maintenance of high species richness in southeastern grasslands. In the Great Plains, this “pyric herbivory” produces higher species richness of plants and several animal groups than either fire or grazing alone (e.g., Fuhlendorf et al., 2008). Either bison or cattle (properly managed) appear able to play this keystone role. Pyric herbivory is not yet well documented in the Southeast, but given the long history of large herbivore activity in this region, it is highly likely to occur here.

Other Disturbances and Combinations

Most grasslands are disturbance-prone communities, and disturbance helps keep them free of trees or with open as opposed to closed tree canopies. Besides fire, many other disturbances damage tree canopies and promote a grass-dominated ground cover. Windstorms (hurricanes, tornadoes, etc.) and ice storms play this role frequently in the southeastern United States. As noted earlier, canebrakes in floodplains may require a combination of large canopy disturbances followed by fire or flooding. Besides the canopy disturbances produced by windstorms and ice storms, the extinct passenger pigeon probably facilitated canebrake development (Noss, 2013).

Along rivers, occasional flooding and ice scour also can maintain grasslands. These riverscours prairies or glades are well developed in several parts of the Southeast, including along the Potomac River in the vicinity of Washington, DC, on rivers of the Allegheny Plateau of West Virginia and Pennsylvania, on some rivers in the Blue Ridge province, in the Ohio River Valley (e.g., Adams County in southern Ohio), on the Cumberland Plateau and Interior Plateaus, and in the Ouachita Mountains of Arkansas and Oklahoma.

Why Are Southeastern Grasslands So Biologically Diverse?

The grasslands of the southeastern United States are some of the most species-rich and endemic-rich grasslands in the world, especially in the temperate and subtropical zones. At a fine scale, a near-record-high richness of 52 vascular plant species in one square meter was recorded in a longleaf pine savanna in the Green Swamp of North Carolina (Walker and Peet, 1984). On a broader scale, several regions of the Southeast are among the biologically richest regions in North America. In particular, the originally grassland-dominated Coastal Plain is now recognized as a global biodiversity hotspot because it meets the criteria of having at least 1500 endemic plant species (it has 1816) and suffering at least 70% loss of its original vegetation (it has lost 86%) (Noss et al., 2015). Some 85% of the plants endemic to the Coastal Plain are associated with pine savannas and embedded communities such as depression wetlands; these are mostly herbaceous grassland plants dependent on frequent fire.

Some factors that explain the high biodiversity of southeastern grasslands are the following:

- Relative climatic stability for long periods of time in this unglaciated region reduced extinction rates and fostered the retention of ancient lineages (paleoendemics) and survival of recently-evolved taxa (neoendemics).
- In the Coastal Plain, sea-level fluctuations promoted allopatric speciation on higher elevation sites surrounded by ocean during high sea-level stands (as did isolation by rivers).

- Several regions contributed species to the Southeast over time, including regions as distant as the western United States, Mexico, Central America, and the Caribbean.
- Frequent disturbance, especially by fire, wind, or large herbivores, prevents competitive exclusion (e.g., in pine savannas, maximum plant species richness occurs at the highest fire frequencies).

Southeastern Grasslands and Carbon Storage

People concerned and knowledgeable about climate change now recognize that in addition to reducing emissions of greenhouse gases, we must also increase the capture and storage of carbon in natural ecosystems. Therefore, protection and restoration of natural areas on vast scales is a necessary component of climate change mitigation. Most attention has been given to forests in this regard. Some plans even include afforestation, which involves planting trees in native grasslands and does more harm than good from a biodiversity conservation perspective. On a global scale, grasslands potentially store as much or even more carbon than forests. Moreover, more of the stored carbon in grasslands is belowground, where it is secure from fire and other disturbances that release carbon.

In grasslands dependent on disturbance to reduce tree encroachment, which most are, fire and large herbivores maintain herbaceous plant cover and diversity. Although fire releases carbon to the atmosphere, this loss of carbon is temporary, since the rapid and prolific plant regrowth after fire quickly takes up carbon dioxide from the atmosphere. In addition, the dung produced by herbivores and the charcoal produced by fires store abundant carbon.

Besides the legendary long roots of prairie grasses, which are often longer and contain much more biomass than the aboveground parts, many grassland plants have generalized or specialized underground storage organs. These fascinating structures store abundant, concentrated carbohydrates, which the plants utilize to resprout after disturbances remove their aboveground parts. Underground storage organs are best developed in plants of tropical and subtropical grasslands. In the southeastern United States, the subtropical grasslands of peninsular Florida are the center of abundance of these “underground forests.”

What Is the Future for Southeastern Grasslands?

As noted earlier, the grasslands of the southeastern United States have suffered devastating declines—greater than 90% for most types. The forces that reduce grasslands, most importantly agricultural and urban development and fire exclusion, show little sign of abating. On the other hand, although traditionally conservationists in the United States have been far more interested in forests than grasslands, a grasslands conservation movement has been steadily growing over the last several decades. Although this movement was initially confined mostly to the Great Plains and Midwest, and to some extent California, it has spread to the Southeast. For example, the Southeastern Grasslands Initiative “aims to preserve, restore, and promote native grasslands of all types throughout the Southeast” (<https://www.segrasslands.org>).

What does the future hold for southeastern grasslands? The most vulnerable grasslands in the region, in general, are probably coastal grasslands, which are threatened by a combination of increasing coastal development and rapid sea-level rise. Elsewhere, all else being equal, the current trend toward a warmer and drier (or more droughty) climate in the region should favor grasslands over forests, as has happened during many similar climatic intervals in the past (Noss, 2013, 2018). Moreover, some models predict greatly increasing lightning activity (Romps et al., 2014), which should benefit grasslands if at least some of the additional fires are not suppressed. However, humans now control land use across the region and are perfectly capable of suppressing most fires and preventing any widespread recovery of grasslands. In the end, the fate of grasslands rests on how we treat them—protection, restoration, and management versus continued destruction.

Abstract

California is one of five biological “hotspots” in the terrestrial temperate zone, all of which occur in Mediterranean-type climate regions. Chaparral is a dominant vegetation type in California, dominated by evergreen sclerophyllous shrubs. This vegetation occurs throughout the California Floristic Province, from northern Baja California to southern Oregon, and contains more than 20% of the flora of California, mostly as postfire herbaceous annuals. Chaparral occurs on poor shallow, soils, and often on steep slopes. Summer drought and fire, along with poor soils, are the main selective agents on the vegetation.

What Is Chaparral?

Chaparral is a shrub-dominated ecosystem in western North America (Keeley and Davis, 2007; Parker et al., 2016). Tough, evergreen shrubs and small trees characterize chaparral in California that makes up over 9% of the wildland vegetation in California (Parker et al., 2016). This nearly impenetrable (to humans) vegetation is one of the most biologically diverse ecosystems in California with numerous animals and over 1400 plant species (over 20% of the California flora) (Parker et al., 2016; Halsey and Keeley, 2016; Jennings, 2018). Many of these species are of limited distribution and are considered rare or endangered (Vasey and Parker, 2014; Keeley, 2018). Principally found on thin, rocky soils in topographically diverse mountains, chaparral dominates much of the coastal regions, southern California, and Sierra Nevada mountain landscapes (Fig. 1).

Chaparral is a dominant vegetation type in the California Floristic Province, an area encompassing most of the nondesert areas of California, as well as northern Baja California and southern Oregon. The region experiences a Mediterranean-type climate with mild wet winters and warm but rain-free summers. The consequence is strong selection for drought tolerance and adaptations to fire. The leaves of the dominant shrubs are usually small and strongly sclerophyllous. Plants exhibit a variety of adaptations to fire regimes. Analogous vegetation types occur in the four other similar climatic regions; *maquis* or *garrigue* in the Mediterranean basin, *fynbos* in the Cape Region of South Africa, *kwongan* in western and southern Australia, and *matorral* in central Chile (Rundel, 2011; Rundel et al., 2016). These five Mediterranean-type climate areas are recognized as areas of high biological diversity, with their floras totaling around one-sixth of the global flora in only about 2.2% of the land area (Cowling et al., 1996; Rundel, 2018). Each region is characterized not only by high diversity, but also by high endemism in multiple lineages. Within North America, chaparral-like shrub-dominated ecosystems extend into Mexico and the mountains of the western United States, but these areas have more summer rainfall and their species and dynamics differ in many characteristics (e.g., Keeley et al., 2012a).

Chaparral varies in species dominance among sites consistent with its extensive geographic distribution. More than 100 shrub species can be found in chaparral but any single site generally contains only a few. Variation in soil types and local climatic conditions are major drivers of composition and dominance shifts among locations. One species, *Adenostoma fasciculatum* (Rosaceae), is widespread and can be found in almost all lower elevation sites (Fig. 2). Two shrub genera have radiated within chaparral, *Arctostaphylos* (Ericaceae) and *Ceanothus* (Rhamnaceae). Shrub oaks (*Quercus* species, Fagaceae) and silk tassel bushes (*Garrya* species, Garryaceae) also have multiple species restricted to chaparral. At higher elevations *Adenostoma* species drop out, but species from the other common genera continue to dominate. Small trees from the genera *Hesperocyparis* (Cupressaceae) and *Pinus* (Pinaceae) are common members of lower elevation chaparral, and other trees may invade chaparral between fires. In more northerly stands and at higher elevations, chaparral is usually found in mosaics with mixed evergreen or conifer forests across the landscape (Fig. 3). Annuals, herbaceous perennials and suffrutescents make up a majority of species in chaparral, but they are common only in the first few years after fire and generally decline rapidly as the shrub canopy closes postfire.

Fig. 1 Distribution of chaparral in California (chaparral also extends into SW Oregon to the north, and into Baja California to the south). Chaparral is divided into a lower elevation vegetation that also exhibits the high diversity postfire annuals and herbaceous perennials. The higher elevation chaparral contains similar woody species but the postfire display is low in diversity. Figure based on data from Cal Fire, Fire Resource and Assessment Program (FRAP) and modified with permission from a figure in Parker, V. T., Pratt, R. B. and Keeley, J. E. (2016). Chaparral. In Mooney, H. and Zavaleta, E. (eds). *Ecosystems of California—A source book*, pp. 479–508. Berkeley: University of California Press.

Origins of Chaparral

Fossil floras indicate that most chaparral shrub taxa trace their origins to at least the Eocene epoch. These floras were mostly east of California as geological processes were still actively forming a terrestrial California. By the middle Miocene, typical genera of chaparral dominants were found in fossil floras in western Nevada and eastern California. The combination of species now observed in chaparral is presumed to have depended on the origin of a Mediterranean-type climate. The timing of when this climate was established in California has been argued to be as early as the mid-Miocene (Keeley et al., 2012b; Rundel et al., 2016) or as late as the Pliocene or early Pleistocene (Axelrod, 1989). Regardless, a Mediterranean-type climate undoubtedly sorted the floras and enabled those genera with evergreen sclerophyllous leaves and other adaptive traits to expand (Axelrod, 1989; Ackerly, 2004; Keeley et al., 2012b). The Mediterranean-type climate varies considerably in California (Fig. 4) (Abatzoglou et al., 2017), acting as one of the driving processes for the variation observed in chaparral. Northern California (e.g., Marin County, Fig. 4) experiences considerably more precipitation due to a higher frequency of winter frontal systems. Southern California (e.g., Los Angeles County, Fig. 4) experiences higher average temperatures than regions to the north. There is also a gradient in maritime conditions; these are coastal fog or relatively low elevation cloud cover with much cooler temperatures in summer only a few kilometers from hotter

Fig. 2 *Adenostoma fasciculatum* dominated chaparral from Southern California. Other species include *Quercus berberidifolia* and others.

Fig. 3 Montane chaparral at over 2200 m in the northern Sierra Nevada on volcanic soils. Chaparral at higher elevations forms dense stands dominated by different mixtures of *Arctostaphylos patula*, *A. nevadensis*, *Quercus vaccinifolia*, *Garrya fremontii*, *Ceanothus cordulatus*, *C. velutinus*, *C. prostratus*, *Prunus emarginata*, and others. These sites are well above the winter permanent snowline and experience a more condensed growing season than lower elevation sites.

inland conditions. Such maritime conditions are frequent in the summer in northern and central California, declining generally southward down the coast. A high proportion of Marin County's land area directly experiences summer fog or moderated temperature (Fig. 4) such that, even with a range of summer temperatures in different locations, the county average temperature is considerably reduced in summer. Areas with breaks in the north-south ranging coastal mountains permit maritime condition to penetrate farther inland in areas like the San Francisco Bay, Monterey Bay, and Morro Bay. South of Point Conception, where ocean currents shift, maritime conditions persist, but are much more limited in impact. Considerable variation thus exists in California's Mediterranean-type climate.

Many of the species found in chaparral appear to have arisen prior to the development of a Mediterranean climate and are consider paleo-endemic taxa in chaparral, such as the widespread dominant *Adenostoma*, but also other genera like *Pickeringia*

Fig. 4 Temperature and precipitation profiles for four counties in California. The counties, from north to south, are Marin, Monterey, San Luis Obispo, and Los Angeles Counties. The data are average monthly temperature and average monthly precipitation. The lines peaking in the summer represent temperatures (*left y-axis*), while the lines at zero in the summer represent precipitation (*right y-axis*). Temperatures are higher in southern California and decline to the north, especially in summer. Note that the summer lacks precipitation in all locations. Precipitation peaks in the winter and is higher in the northern regions. Data are from Abatzoglou, J. T., McEvoy, D. J., and Redmond, K. T. (2017). The west wide drought tracker: Drought monitoring at fine spatial scales. *Bulletin of the American Meteorological Society*. doi:10.1175/BAMS-D-16-0193.1.

(Fabaceae) and *Dendromecon* (Papaveraceae). The modern chaparral flora represents combinations of these older lineages, along with considerable and more recent immigration from regional floras. The high levels of endemism in chaparral are principally found in the postfire herbaceous flora as only two shrub genera have extensively diversified, *Arctostaphylos* (Ericaceae) (Boykin et al., 2005; Wahlert et al., 2009) and *Ceanothus* (Burge et al., 2011).

Drought and Wildfire: Key Processes of Ecology and Evolution

California averages a much smaller amount of summer rain than other Mediterranean-climate regions (Keeley et al., 2012b), suggesting greater selection for drought-tolerating traits that can aid plant survival. When researchers point out the lack of summer rain in Mediterranean-climates, one aspect that frequently lacks emphasis is the small total amount of precipitation. Most areas in California with chaparral average only around 400–600 mm annual precipitation. Because annual patterns can vary 20% or more between years, in dry years water stress can be considerable, while in wet years, total precipitation can still be less than most temperate regions. Rather than rare events, then, normal fluctuation in aspects of climate can be significantly stressful, occurring multiple years in every decade (Cowling et al., 2005; Cayan et al., 2008; Dettinger, 2016).

Physiology and Drought Stress

As a consequence of the lack of summer rain, drought-adapted shrubs dominate chaparral (Mooney, 1989). The lack of summer moisture constrains the growth and productivity of these species. Precipitation, however, falls in the winter and spring when temperatures are relatively low and days are shorter in photoperiod. Growth and metabolism of these plants then is regulated by low soil moisture in the summer and fall, shifting photoperiod, and temperature (Mooney et al., 1975, 1977; Davis and Mooney,

1986). These factors create a strong seasonal cycle with assimilation peaking in spring and early summer, and water conservation emerging as a constraint in late summer and fall (Parker et al., 2016).

The presence of evergreen leaves of the dominant shrubs allows photosynthesis to occur throughout the year. More active rates of photosynthesis occur following rains in the fall and winter, although the daylight periods are shorter and temperatures are cooler. Even with cooler temperatures, photosynthesis continues near optimally during winter and early spring (Oechel et al., 1981; Mooney and Miller, 1985; Parker et al., 2016). Chaparral shrubs are able to photosynthesize at relatively maximal rates over a broad range of temperatures (10–30°C) (Mooney et al., 1975; Oechel et al., 1981). Consequently, rates of photosynthesis and growth are moderate in winter and tend to increase throughout the moist spring as temperatures warm along with longer day lengths. Leaf structure is compromised between maximizing rates of carbon assimilation versus water conservation and survival of low water potentials. Leaves are low in specific leaf area (SLA), which makes them mechanically strong and better able to tolerate water stress. Sclerophyllous leaves, however, limit the maximum potential rates of carbon assimilation and summer drought can further restrict photosynthesis as plants reduce transpiration by stomatal control (Pratt et al., 2007) (Fig. 5).

Chaparral principally occurs in shallow, rocky soils on equator-facing slopes. Rooting depth becomes a major organizing concept with respect to species distribution patterns within chaparral and what types of adaptive characteristics they may exhibit. Species with deeper roots as adults can avoid water stress for longer time periods, but tend to be distributed in more mesic sites, like polar-facing slopes or ravines. Constraints on seedling establishment are probably responsible for this initially counterintuitive pattern. *Heteromeles arbutifolia* and *Rhus laurina* (Anacardiaceae) are good examples. Species dominating ridges or equator-facing slopes tend to have shallower rooting systems but with vascular structures able to withstand lower water availability (Jacobsen et al., 2007); *Ceanothus* and *Arctostaphylos* species are typical of this group. Most species tend to fall between the extremes, but using the extremes as representatives of different sets of adaptations, chaparral species have diverged in a number of ways. The more shallow-rooted species will experience much drier soils in the late summer and early fall and experience much greater minimum water potentials (Jacobsen et al., 2007; Pratt et al., 2007). They also tend to have strong stem cavitation resistance, close their stomata at much lower water potentials, and have denser and stronger xylem (Jacobsen et al., 2007; Pratt et al., 2007, 2008). These plants also have tracheids associated with vessels (vasicentric tracheids) (Carlquist, 1989), thought to provide an adaptive back-up water source for leaves should cavitation occur in the main vessels. Species with deeper roots tend to have larger, slightly more mesic leaves and be more sensitive to dry conditions, especially as seedlings (Parker et al., 2016).

Fire and Adaptive Responses

A consequence of the seasonal droughts is a fire regime. The relatively low stature of chaparral (generally 2–6 m) and continuous canopy structure means that fire will carry through the canopy and consume nearly the entire above-ground biomass. Consequently, these are fairly intense fires, but vary in intensity within and among fires depending on environmental conditions. Multiple dimensions make up the chaparral fire regime (Keeley and Safford, 2016). The frequency of fire is variable but generally occurs

Fig. 5 Close up of the sclerophyllous leaves of *Ceanothus cuneatus*. These leaves are only about 2 cm in length and provide an example of some of the leaf type most chaparral species exhibit. Some species have leaves that are more needle-like, in others the leaf blade is larger; some are cupped upward, others flat or rolled in on the lower surface.

between 30 and 100 or more years. Historical records are lacking for vegetation of this type, but given the presence of serotinous conifers and other types of data, together they indicate this is a natural range, especially given the climatic variation in distribution for chaparral (van Wageningen and Cayan, 2008; Van de Water and Safford, 2011; Safford and Van de Water, 2014; Parker et al., 2016; Syphard and Keeley, 2016; Keeley and Syphard, 2017). Fires historically tended to peak in September at lower elevations as the vegetation began to dry. This follows fruiting and dispersal for most species. Fire severity is moderate to high, and variations in local severity can favor different sets of species arising from the seed bank. Other aspects can sometimes be important, depending on environmental conditions. Historically lightning was the primary source of ignition, but with the expansion of human infrastructure and population densities, accidental ignitions by people are now the most common ignition sources (Keeley and Syphard, 2018). In the past century, as population density increased, so too did fire ignitions. Since around 1980, however, ignitions have begun to decrease while area burned has stayed relatively constant (Keeley and Syphard, 2018).

Chaparral dynamics therefore reflects the pattern of fire, postfire recovery, and maturation, all in the context of fluctuating drought conditions. Variation in fire frequency, intensity and other conditions within the normal fire regime favor different sets of species. The first postfire year is characterized by a diverse group of annuals, suffrutescents, and species with bulbs and corms. Fire also stimulates their postfire germination or emergence due to both the fire's heat pulse into the soil or due to chemicals from smoke that the first winter rains wash into the soil (Keeley, 1987, 1991; Keeley et al., 2012b). The annual populations remain for one to several years; the seed produced during those years remains dormant in the soil until the next fire (Figs. 6 and 7). The herbaceous perennials and suffrutescents persist until the dominant shrubs close the canopy of the vegetation (Fig. 8). Many of these herbaceous perennials and suffrutescents also produce dormant, persistent seed banks. These are very diverse groups of species, with representatives from a number of plant families like Fabaceae, Lamiaceae, Polemoniaceae, Onagraceae, Papaveraceae, Hydrophyllaceae, Liliaceae, and Melanthiaceae among others (Keeley and Davis, 2007; Parker et al., 2016; Keeley, 2018).

Most woody plants in chaparral are capable of surviving fire due to underground stems, root crowns, or enlarged woody bases containing a high density of dormant buds (burls). In the first postfire year, surviving shrubs resprout and grow rapidly so that within a few years the stand has closed the canopy again and a continuous layer of vegetation covers the landscape. Most of these shrubs recruit new individuals only in the shade of older stands so their persistence requires their ability to survive fires. These shrubs are referred to as obligate sprouters and examples are species from *Grassia*, *Heteromeles*, *Frangula* (Rhamnaceae), and *Quercus* among others (Fig. 9) (Table 1). Three chaparral shrub genera, *Adenostoma*, *Arctostaphylos*, and *Ceanothus*, have developed seed that partially or completely remain dormant until stimulated by fire, either due to a heat pulse into the soil or from chemicals found in smoke (Keeley, 1987, 1991, Parker and Kelly 1989). In the first postfire year, shrubs resprout and seed from the soil seed bank germinate and recruit new individuals; these plants have been referred to as facultative seeders (Table 1; Fig. 9). A different life history has also developed in some species in the latter two of these genera, *Arctostaphylos* and *Ceanothus*. In these species the adults are killed by fire and the population is completely dependent on seedling recruitment emerging from the soil seed bank to maintain their populations. Because of this pattern, these species have been referred to as obligate seeders (Table 1; Fig. 10). A similar life history occurs in some of the conifers associated with chaparral. The cones of some lineages of *Pinus* and *Hesperocyparis* remain closed after maturation and are opened by the heat of the fire, a condition referred to as serotiny. The adults of these trees are killed and the population recruits from the postfire dispersal from the cones. They are also obligate seeders but utilize their closed, serotinous cones as aerial seed banks. Chaparral also occurs in landscape mosaics with other vegetation types, especially a variety of forests. In those circumstances, trees may invade chaparral during fire-free periods, but are usually eliminated by canopy fires unless they are able to resprout (Table 1).

Fig. 6 *Chorizanthe pungens* var. *hartwegiana* (Ben Lomond spineflower), a rare species except after fire, an example of the annual diversity in the postfire years.

Fig. 7 *Phacelia suaveolens* (sweet scented phacelia) is a pyrophyte in the sense that you see it after fires and then it remains only as seed in the soil until the next fire. A number of *Phacelia* species throughout the range of chaparral are abundant in the postfire years.

Fig. 8 *Xerophyllum tenax* (bear grass) is a herbaceous perennial species in the Melanthiaceae, a family of the Liliales. This plant can rarely be found flowering except in the years following a fire. Native Americans would burn areas with this plant because the leaves in the first year or two following fire can be used for baskets (hence the other common name, basket grass).

Among these species, aspects of physiology diverge with respect to characteristics of the habitat for germinating seed and seedling establishment. This is clear when examining woody species. Those taxa that are obligate sprouters establish seedlings in the shade of mature chaparral, their physiology matches the requirement of seedlings being somewhat shade tolerant and more mesic (Pratt et al., 2010). Obligate and facultative seeders establish seedlings in open, postfire habitat with high light and variable temperatures; they are generally shade-intolerant. These seedlings have to grow roots rapidly to survive and indeed most seedlings do not survive the first summer-fall dry period. Overall, then, chaparral illustrates a range of species with respect to fire regimes, from those with no obvious adaptations but exploit fire free periods, to those whose populations are adapted to and dependent on fire to recruit new individuals.

Fig. 9 Chaparral response in the first growing season following a fire. Shrubs here are resprouting, with most of the site dominated by *Quercus wislizenii* var. *frutescens*, an obligate sprouter, with *Arctostaphylos glandulosa*, a facultative seeder, in the right foreground appearing a little grayer.

Biological Diversity of Chaparral

Chaparral is one of the most diverse vegetation types in California, with over 20% of the flora comprising part of chaparral. The majority of species are seen only in postfire circumstances, either their regeneration being tied to fire stimulation of germination or their abundance limited by the closed canopies of the dominant shrubs prior to fire (Keeley and Davis, 2007; Parker et al., 2016). Thus variations in fire regimes are fundamental drivers of diversity found in chaparral and as human populations increase and modify fire regimes, such changes may be a large influence on future chaparral diversity as we will focus on later.

The postfire arena exhibits over three-quarters of the chaparral flora, principally as annuals or herbaceous perennials. Many of these are essentially endemic to chaparral, such as a variety of species from the Hydrophyllaceae (e.g., *Emmenanthe penduliflora*, *Phacelia brachyloba*, *P. grandiflora*, *P. sauevolens* among others), Papaveraceae (e.g., *Ehrendorferia chrysantha*, *E. ochroleuca*, *Papaver californicum*), Polemoniaceae (e.g., *Allophyllum glutinosum*, *A. giliodes*, *Saltugilia australis*) among others (Keeley and Davis, 2007, Parker et al., 2016). These species generally occur patchily across the landscape and are dependent on local and historical conditions; local referring to site fire severity, and current patterns of precipitation and temperature, while historical mainly refers to dispersal patterns of fires in the past and the climatic conditions associated with past postfire environments.

Suffrutescents, or subshrubs as they are sometimes called, are also common in postfire areas. Most of these have dormant seed banks stimulated by fire. Their rapid growth rates permit their establishment and temporary dominance in the postfire circumstances, slowly being eliminated by woody shrub canopies shading them out through time. Typical species vary among sites, but *Crocianthemum* (*Helianthemum*) *scoparium* and other species in the Cistaceae are widespread; other local dominants include *Eriocameria arborescens* (Asteraceae), *Eriodictyon californicum* (Hydrophyllaceae), *Acmispon glaber* (*Lotus scoparius*) (Fabaceae), *Lepechinia calycina* (Lamiaceae), *Salvia mellifera* (Lamiaceae), *Diplacus* (*Mimulus*) *aurantiacus* (Phrymaceae), and *Eriogonum fasciculatum* (Polygonaceae).

Two woody shrub species have radiated in California chaparral, *Arctostaphylos* and *Ceanothus*. *Arctostaphylos* has about 104 taxa, almost all of which are found in the California Floristic Province (Parker et al., 2012) (Fig. 11). About two thirds of the taxa are obligate seeders while the rest are facultative seeders. The resprouting individuals have large burls, a character lacking in *Ceanothus*. A similar diversity pattern is found in *Ceanothus* comparing facultative versus obligate seeding, with nearly two thirds or more being obligate seeders (Fig. 12). Within *Ceanothus*, however, there is less clarity about whether a species is an obligate seeder or not, and in some lineages, there is a shift in the proportions of individuals among populations that are killed versus those that resprout after fire. *Ceanothus thyrsiflorus*, for example, has a higher proportion of individuals that resprout in its southern distribution, for example, San Luis Obispo County, while almost all individuals are obligate seeders toward northern California. Another species, *Ceanothus tomentosus*, has resprouting populations in the Sierra Nevada foothills, but populations in coastal San Diego County are obligate seeders (Schwilk and Ackerly, 2005). This divergence may result from specialization in different types of habitats, with obligate seeders being favored under different conditions from facultative seeders (Keeley et al., 2016).

Much of the diversity in *Ceanothus* and *Arctostaphylos* is comprised of local endemics, often restricted to areas with maritime influence of moderated temperatures and some frequency of coastal fog (Fig. 13). In the area around the northern San Francisco Bay, for example, a series of species of *Ceanothus* occur on a range of soil types and climatic conditions. *Ceanothus jepsonii* var. *jepsonii*

Table 1 Common plant life form and life history types in California chaparral.

Life form	Life history	Occurrence	Example species	Common name
Tree	<i>Survives only surface fires</i> (no canopy fires)	Generally trees in coast ranges, especially in the more northerly areas or higher elevations in mountains, invades chaparral over time	<i>Pseudotsuga menziesii</i> <i>Pinus ponderosa</i> <i>Abies concolor</i>	Douglas-fir Ponderosa pine White fir
	<i>Obligate sprouter</i>	Coast ranges in central California and more mesic regions; one restricted species in Southern California	<i>Quercus agrifolia</i> <i>Notholithocarpus densiflorus</i> <i>Pseudotsuga macrocarpa</i>	Coast live oak Tanbark oak Big-cone Douglas-fir
	<i>Serotinous or semiserotinous</i> (adults dying, population reestablishes from seed dispersed postfire) (obligate seeder)	In more mesic regions of chaparral environmental gradients, mostly coast ranges, Sierra foothills	Multiple pine species, especially <i>Pinus attenuata</i> , <i>P. radiata</i> , <i>P. muricata</i> , <i>P. sabiniana</i> ; Multiple cypress species, especially: <i>Hesperocyparis sargentii</i> <i>H. macnabiana</i>	Knobcone pine Monterey pine Bishop pine Gray pine Sargent's cypress MacNab's cypress
Shrub	<i>Obligate sprouters</i> (species regenerating later on in fire-free periods in the shade of mature stands)	Widespread and common throughout	Multiple species of shrub oaks, especially: <i>Quercus berberidifolia</i> <i>Q. durata</i> <i>Q. vaccinifolia</i> <i>Q. wislizenii</i> var. <i>frutescens</i> Multiple other species like: <i>Heteromeles arbutifolia</i> <i>Pickeringia montana</i> <i>Garrya elliptica</i> <i>Frangula californica</i> <i>Cercocarpus betuloides</i> <i>Rhus integrifolia</i> <i>Rhus ovata</i> <i>Malosma laurina</i>	California scrub oak Leather oak Huckleberry oak Interior live oak Toyon Chaparral pea Silt tassel Coffee berry Mountain mahogany Lemonade berry Sugar bush Laurel sumac
	<i>Facultative seeders</i> (species resprouting after fires, but recruiting new individuals in the first year or two postfire from dormant, fire-stimulated soil seed banks)	Widespread and common throughout	<i>Adenostoma fasciculatum</i> Several species of manzanitas, especially: <i>Arctostaphylos glandulosa</i> <i>A. tomentosa</i> <i>A. crustacea</i> <i>A. patula</i> Several species of California lilac, especially: <i>Ceanothus leucodermis</i> <i>C. cordulatus</i>	Chamise Eastwood manzanita Woolyleaf manzanita Brittleleaf manzanita Greenleaf manzanita Chaparral whitethorn Mountain whitethorn
	<i>Obligate seeders</i> (species whose adults are killed by fire and recruit new individuals in the first year or two post-fire from dormant, fire-stimulated soil seed banks)	Widespread and common throughout	In California only two shrub genera represent this life history. The majority of species in both genera are obligate seeders, with many local endemics. <i>Arctostaphylos</i> , especially: <i>A. canescens</i> <i>A. glauca</i> <i>A. pungens</i> <i>A. manzanita</i> <i>A. stanfordiana</i> <i>A. viscida</i> <i>Ceanothus</i> , especially: <i>C. cuneatus</i> <i>C. crassifolius</i> <i>C. perplexans</i> <i>C. jepsonii</i> <i>C. thyrsiflorus</i> <i>C. papillosus</i> <i>C. oliganthus</i>	Hoary manzanita Big berry manzanita Mexican manzanita Common manzanita Stanford manzanita White leaf manzanita Buckbrush Hoaryleaf Ceanothus Cupped leaf Ceanothus Musk brush Blue blossom Wartleaf Ceanothus Hairy Ceanothus/Jim brush.

is a serpentine endemic found in one area just north of San Francisco, while closer to the coast and under more summer fog *C. decoratus* is another highly restricted serpentine endemic (Parker, 2014). Along the immediate coast are three varieties of *C. gloriosus* that range from highly restricted endemics to spottily distributed populations up the coast. To the east and north, another highly restricted serpentine endemic, *C. sonomensis* occurs, but farther north being replaced by *C. jepsonii* var. *albiflorus*. On other soil types, *C. purpureus* dominates volcanic soils in the Napa Range, while to the west of the Napa Range, *C. divergens* and *C. confusus* can be found (Parker, 2014). In central and southern California, other examples of local endemism in *Ceanothus* can also be found (Burge et al., 2017). *Arctostaphylos* demonstrates similar patterns of diversity and restricted endemics (Fig. 14). In the San Luis Obispo region of the central coast a series of local endemics are found on diverse soil types (Wells, 1962). In the maritime region around Monterey and San Francisco Bay, jumping down the coast to islands off Santa Barbara are a series of species with leaves unique in the genus having auriculate shapes. These include *A. auriculata* and *A. pallida* in the north, to *A. imbricata*, *A. montaraensis*, *A.*

Fig. 10 Seedlings of *Arctostaphylos andersonii* emerging from a rodent cache in the first postfire spring. This provides an example of both germination of dormant seed that were stimulated by chemicals from the fire, as well as illustrating the mutualistic role of rodents in caching the seeds to a depth sufficient to keep them below the killing heat pulse in the soil during a fire.

Fig. 11 *Arctostaphylos* (manzanita) dominated chaparral from Mt. George, Napa County, Northern California. In the foreground are two different species of *Arctostaphylos* (*A. canescens*, grayish, *A. stanfordiana*, green). On the left foreground several individuals of *Adenostoma fasciculatum* are visible, with very small, needle-like leaves. The landscape in the background is dominated by manzanita chaparral.

andersonii, and others going south to *A. viridissima* on Santa Cruz Island (Parker et al., 2012). In both genera, some of these taxa may have evolved due to hybridization or by ancestral variability constrained by strong edaphic conditions, permitting different genetic combinations to parse local soil and climate conditions (Wells, 1968, 1969; Burge et al., 2011, 2013, 2017, 2018; Parker and Vasey, 2004, 2016; Vasey and Parker, 2014).

Chaparral animals also represent a diverse group. California has considerable mammal diversity including within chaparral areas (Parker et al., 2016; Halsey and Keeley, 2016; Jennings, 2018). While many of these mammal species frequent multiple habitats, some are essentially restricted to chaparral or similar shrub habitats, like *Peromyscus californicus*. These animals can

Fig. 12 *Ceanothus cuneatus* (buckbrush) dominated chaparral in the Sierra Nevada foothills. This *Ceanothus* species and close relatives occupy lower elevation chaparral in the foothills of the Sierra Nevada on a variety of soil types. This figure illustrates chaparral in the Red Hills region where soils are principally serpentine. The site also contains *Pinus sabiniana*, a semiserotinous species, *Adenostoma fasciculatum*, and a few other shrub species sparsely. A number of rare annuals are present during the growing season.

Fig. 13 Maritime chaparral on sand dunes in Monterey County. This site is only a few km from the Pacific Ocean and is dominated by *Arctostaphylos tomentosa*, *A. pumila*, *Ceanothus rigidus*, and *Quercus agrifolia*. Annuals dominate available sandy openings during the growing season.

represent critical ecological processes, such as seed predation and dispersal (Warzecha and Parker, 2014; Parker, 2015), burying seed in some cases to depths and in manners ensuring seed survival (Parker, 2015; Peterson and Parker, 2016) (see Fig. 10). Invertebrates are especially important in chaparral, as key pollinators and components of mineral and energy flow. Over 500 invertebrates, for example, have been found on one species alone of montane chaparral, *Arctostaphylos patula* (Valenti et al., 1997). These are principally herbivores, predators and parasitoids. Coastal plant species also appear to harbor considerable diversity, with over 200 insect taxa found on 26 coastal manzanita species, most of which were foliovores (Andres and Connor, 2003). At least two invertebrate genera have radiated in chaparral. One aphid genus, *Tamalia*, has multiple species, all of which are apparently restricted to *Arctostaphylos* species (Miller III, 2005). *Timena* is a genus of walking-stick insects that have evolved variations in cryptic coloration relating to their host plants, species of *Ceanothus* and *Adenostoma* (Crespi and Sandoval, 2000). Other lineages are richly diverse in chaparral, for example, over 300 bee species are found in chaparral in San Diego County (Halsey and Keeley, 2016).

Fig. 14 Serpentine chaparral in the Laguna Mountain ranges of San Benito County. This inner coast range site is dominated by soils derived from serpentinite. These soils are poor in nitrogen and phosphorus, generally have an imbalance between magnesium and calcium, and are rich in heavy metals. *Arctostaphylos glauca*, *A. pungens*, and *Quercus durata* are the shrub dominants at this site. The pine is *Pinus sabiniana*, a semiserotinous species.

Ecosystem Services

Chaparral is often perceived generally as “worthless brush” or a major fire hazard (Sterling, 1904; Love et al., 1952; Doman, 1967; Rundel, 2018), but much less often as the valuable ecosystem that it actually is. Without trails, chaparral is nearly impenetrable and difficult for people to enjoy. Chaparral does provide considerable ecosystem services, however. The Millennium Ecosystem Assessment (MA) (2003, 2005) defined such services as benefits that people obtain from the functioning of ecosystems. One is clearly the cultural services most natural areas provide to people; the aesthetic of mountain slopes and views, the slopes coming into flower and fruit in different seasons from mid-winter to late summer is something many enjoy.

More critically, functioning chaparral provides all four of the service categories indicated by the Millennium Assessment, including provisioning (such as food, fuel), regulating (such as air and water purification, climate stabilization, hazard mitigation), cultural (such as spiritual, aesthetic and educational enjoyment of nature), and supporting services (such as soil formation, nutrient cycling, biomass production) (Chaplin-Kramer et al., 2016; Parker et al., 2016; Rundel, 2018).

For example, a large proportion of areas dominated by chaparral are moderate to steep slopes, the kind that are subject to erosion, mudslides and debris flows. Chaparral shrubs with their various shallow to deep rooting systems are able to mitigate and constrain these processes, such that danger from debris flows are limited to occasional postfire years with heavy rains (Gabet and Dunne, 2002; Ren et al., 2011; Rundel, 2018).

Stands of chaparral also filter water and produce watersheds that can reduce N pollution and other hazards from precipitation and air pollution. Downstream these services reduce eutrophication in reservoirs and adjacent near-shore regions (Rundel, 2018). At the same time, chaparral is a relatively productive vegetation, even in older stands, and consequently provides considerable biomass and carbon sequestration. The shrub canopies also mitigate the heat island effect of adjacent developed regions, a critical feature as climate change predicts increasing temperature (LaDochy et al., 2007; Rundel, 2018).

In addition to these types of ecosystem processes, chaparral vegetation is a habitat for a large number of fungal and animal species. Extensive chaparral provides significant pollination services beyond its own boundaries (Kremen et al., 2004). The large number of organisms indicates extensive food webs, which provide wildlife value for birds and mammals not restricted to chaparral.

Threats to Chaparral Conservation

Mediterranean climate ecosystems globally are highly threatened for diversity loss due to increasing habitat loss and climate change (Sala et al., 2000; Stein, 2002; Underwood et al., 2009). In California, urban and agricultural expansion has replaced roughly 75% of all natural vegetation, including considerable chaparral (Brooks et al., 2004). Currently, most chaparral management practices are focused on fire and fire hazard rather than on practices that would sustain or enhance this ecosystem and its services. Many people seem to have a perspective that they are separate from natural processes, and when something is a negative or threatening feature of the region, they desire to reduce it as much as is possible. Treating chaparral only as a fire hazard is a principal issue today.

One critical threat is the over-generalization of fire-type vegetation. Chaparral is resilient to fire within a range of frequencies, severities, and timing that it has historically experienced, a pattern that varies among locations such as the foggy maritime chaparral along the coast, to drier inland sites, to higher elevation montane chaparral above the winter snowline. When articles appear in the press concerning fire, chaparral is frequently lumped with forests and the whole state of California is seen in a homogeneous perspective. The reality, however, is that fire regimes vary considerably among vegetation types (Keeley and Safford, 2016) and considerably within those different vegetations (Syphard and Keeley, 2016; Keeley and Syphard, 2017; Parker et al., 2016). The application of a single fire concept and ignoring locally and regionally unique responses in such a variable ecosystem is destructive. For example, poor timing of management, like reducing fuel load by burning chaparral under moist and cool conditions when it is safer to control, considerably reduces the ability of chaparral to recover, especially from the persistent soil seed bank (Doman, 1967; Parker, 1987, 1989, 1990, 1993; Le Fer and Parker, 2005). Not recognizing variation in species composition also threatens chaparral recovery from fire. Increases in fire frequency eliminates obligate seedling species and permits non-native annual plants to invade, degrading the system function (Zedler et al., 1983; Haidinger and Keeley, 1993). Similarly, introducing large scale fire breaks provides a corridor for invasive annuals that limit chaparral postfire recovery (Keeley, 2006; Halsey and Keeley, 2016). These are issues throughout global Mediterranean-type climate shrub ecosystems (Keeley et al., 2012b).

Fire hazard concern also emphasizes one of the greatest threats to chaparral, which is increasing population and encroachment of communities into wildland areas. Increased frequencies of fires associated with human expansion and strong desert winds in Southern California has resulted in type conversions in a number of sites. Because people are the most common source of ignitions in California (Syphard et al., 2007, 2017; Keeley and Syphard, 2018), increased fire frequency has been followed by calls for intensive (mis)management of chaparral. The total number of fires has been declining for the past 50 years (Keeley and Syphard, 2018), but the eight of the largest and mostly deadly fires have been in the past decade. Human ignitions in the context of climate change in chaparral areas adjacent to exurban and urban housing is an increasingly unsafe and ecologically destructive combination.

Climate change thus may represent a significant threat as well. A narrowed rainy season combined with higher summer temperatures means the potential for fire increases from 4 to 6 summer to early fall months, to nearly year-round conditions. Changes in ocean temperatures and currents along the California coastline may reduce the frequency and persistence of coastal fog (Johnstone and Dawson, 2010). Such a modification of coastal environments potentially threatens California's maritime chaparral in these regions (Vasey et al., 2012). These maritime habitats contain a majority of the woody rare and endemic chaparral species (Vasey et al., 2014; Vasey and Parker, 2014). Finally, impacts on mutualisms may be substantial, such as for populations of pollinators (Memmott et al., 2007).

Recent decades have also witnessed the introduction of multiple pathogens, particularly species in the genus *Phytophthora*, which can injure and sometimes kill numerous chaparral species. The genus *Arctostaphylos*, the most diverse woody plant genus in chaparral, may be particularly sensitive to some *Phytophthora* (Swiecki et al., 2003, 2017). While these pathogens are management problems in protected areas, habitat loss and destruction due to fire hazard management remain the principal issues.

Animals within chaparral are also increasingly at risk as development encroaches on natural areas. In addition to the direct loss of habitat that results from the clearing of chaparral to make way for developments, development adjacent to and human activity within wild areas appears to change the distribution and reduce the richness of wildlife (Sauvajot et al., 1998; Ordeñana et al., 2010; Šálek, 2014). In some cases it results from domesticated animals that prey on birds or rodents (Crooks and Soulé, 1999). Recent research indicates human development causes substantial changes in mesopredator distribution and temporal responses, and also shifts in their feeding niches (Wang et al., 2015; Gaynor et al., 2018; Smith et al., 2018).

Future of Chaparral

Climate change and increasing population density in California make predicting the future of chaparral difficult (Parker et al., 2016). Recent dieback from extended droughts in southern regions of California (Paddock III et al., 2013) indicate that fluctuations in future climate may impact chaparral considerably (Hayhoe et al., 2004; Cayan et al., 2008; Dettinger, 2016). Shortened rainy season and increases in temperature will extend the fire season for most areas of the region. Changes in climate and fire regimes will combine to drive changes in the composition and distribution of chaparral (Keeley and Syphard, 2016). Management practices that treat chaparral primarily as a fire hazard and increases in invasive species will further alter fire regimes and distribution patterns, cascading into the food webs of the ecosystem and the services provided.

Chaparral is a biotically diverse and abundant vegetation in California. The fact that fire regimes are a critical aspect of the dynamics and regeneration of the ecosystem leads to conflicts with human occupation on the landscape. No policies have yet been produced and implemented that balance conservation of chaparral with safety for urban and exurban developments. Recognition of the ecosystem services provided by chaparral, as well as the biodiversity spread across the state, will aid in a future accommodating both chaparral and human development. Considering current management practices in a context absent of fire crises will be necessary to achieve such balance.

Abstract

California's oak savannas and associated grasslands occupy roughly 3 million ha. They are defined by the presence of scattered oak trees, in monospecific or mixed stands, with an herbaceous ground cover, composed predominantly of annual grasses and forbs. Supporting natural communities rich with native flora and fauna, oak savannas and grasslands contribute significantly to the designation of the California Floristic Province as a "biodiversity hotspot". These systems also provide numerous benefits to humans: in the past sustaining indigenous cultures who depended on oak acorns for food, and in the more recent past and present as a source of wood, timber, livestock grazing, and recreation. Climate in California's oak savannas is Mediterranean, with cool, wet winters and hot, dry summers. Both climate and soil type exert broad control on the distribution of grasslands and co-occurring woody vegetation in California. At a finer scale, plant and animal interactions strongly influence community structure and dynamics, as do human impacts such as livestock grazing and the use of fire. Two of the most significant threats to the longterm sustainability of California's oak savannas and grasslands are land-use conversion to agriculture and residential development, compounded by low rates of natural regeneration in extant stands of oaks.

Introduction

Savannas are generally defined as open woodlands, composed of scattered trees over an herbaceous ground layer. In California's oak savannas the tree canopies are generally not overlapping, and oak trees comprise between 10 and 30% of the vegetative cover (Griffin, 1977; Grossman et al., 1998; Allen-Diaz et al., 1999; Sawyer et al., 2008). Grassland, characterized by herbaceous graminoid and forb species (Grossman et al., 1998; Sawyer et al., 2008), dominates in the intervening spaces between the trees and extends under the oak canopies. Thus, California oak savannas include components of both tree-dominant woodland and herbaceous-dominant grassland. In some oak savannas the understory may also include shrubs associated with chaparral or coastal sage scrub plant communities.

As has been described for other savanna ecosystems (Taft, 1997; Anderson et al., 1999), California oak savannas lie on a continuum from grassland to forest, and they often occur in a mosaic of grassland, shrubland, and woodland communities (Fig. 1). Depending on the spatial and temporal scale that observations are made, the boundaries of those community-types may not always be clearly demarcated. While some attributes, such as species composition and climate conditions, of the continuum “end points” described above (distinct grassland and oak forests) overlap with oak savanna, this article primarily focuses on savannas and their corresponding grassland communities.

Distribution

Oak dominated landscapes (forests, woodlands, and savannas) occupy roughly 4.5 million ha, or approximately 11% of the state of California (Davis et al., 1998). The more open landscapes—oak woodlands and savannas—have generally been considered a single “type” (e.g., 10–60% tree canopy cover) in hardwood inventories and wildlife assessments (Davis et al., 2016). However, it has been estimated that between 2.1 million ha (Davis et al., 2016) and 3.8 million ha (Allen-Diaz et al., 1999) in California are classified as oak savanna/grassland (i.e., 10–30% tree canopy cover).

The five species of arborescent oaks that are predominant in California’s oak savannas are blue oak (*Quercus douglasii* Hook. & Arn.), valley oak (*Q. lobata* Née), coast live oak (*Q. agrifolia* Née), interior live oak (*Q. wislizeni* A. DC.) and Englemann oak (*Q. engelmannii* Greene) (Fig. 2). These may be present in monospecific or mixed stands. Several previous articles characterize oak savannas as distinct vegetation communities or types (e.g. valley oak savanna, blue oak savanna, mixed oak savanna) (see Allen et al., 1991, and Allen-Diaz et al., 1999). Many of the key species co-occur (e.g., blue oak savanna, dominated by blue oak, may also include valley oak, interior live oak, and coast live oak) or are present in nearly all sites (e.g., many species of nonnative annual grasses). In addition, many of the ecological characteristics are similar among all these types. Thus in this article, we will focus on the distributions of each of the dominant tree species, with their common co-dominants and ranges, and elsewhere describe factors that are similar across all of these savannas.

Oak savannas dominated by blue oak, valley oak, and interior live oak, are found in a ring around the Central Valley along the inner Coast and Transverse Ranges and Sierra Nevada foothills. Coastal oak woodlands and savannas are dominated by coast live oak. Englemann oak savannas occur in a more geographically restricted distribution in the Peninsular Ranges. All occur primarily within an elevation range of 60–700 m (Allen-Diaz et al., 1999).

Although not the subject of this article, the unique oak woodlands found on the California Channel Islands ought to be mentioned, as they occasionally occur in relatively open settings, similar to the savannas on the mainland. Island oak (*Q. tomentella* Engelm.) is an evergreen tree and an insular endemic (Sawyer et al., 2008). Most often in north-facing slope and moist canyon habitats, island oak is present in dense groves and woodlands, co-occurring with coast live oak (*Q. agrifolia*), canyon live oak (*Q. chrysolepis*), and Catalina ironwood (*Lyonothamnus floribundus* A. Gray). The endemic island scrub oak (*Q. pacifica* Nixon & C.H.

Fig. 2 California oak savanna and woodland landscapes as mapped by the California Gap Analysis Project (Davis et al., 1998). Characteristic dominant or co-dominant oak species are shown. Species may occur in mixed oak or oak-pine savannas but for legibility only one characteristic oak species is shown. The mapped species may also occur in less extensive areas beyond those mapped here. Map produced by F. W. Davis.

Mull.) can form woodland and savanna-like communities where individual shrubs reach treelike stature, especially on the uplands of Santa Catalina and the isthmus of Santa Cruz (Junak et al., 2007).

Climate and Soils

The climate in California's oak savannas is Mediterranean, with cool, wet winters and hot, dry summers. Over 90% of precipitation falls between December and March, with an extended summer drought. Foothill savanna oak species occur in locations that experience 40–80 cm of winter rainfall, and mean annual temperatures of 14–17°C (Davis et al., 2016).

The various oak species occur in many ecological settings including slopes, alluvial terraces, valley floor and some ridge-top environments. Oak savannas may be found on a wide variety of soil-types from rich loams in the valleys to thin, rocky or sandy soils on upland slopes, with the different oak species tending to occupy different settings and soil-types. For example, valley oak tends to occupy deep, relatively fertile valleys or canyon bottoms, while blue oak may be more common on drier slopes with rocky soils, but there are sites where these species co-occur.

Biodiversity: Key Species

Rich in both flora and fauna, California's oak woodlands and savannas support thousands of understory and grassland plant species, thousands of invertebrate species, and over 300 species of vertebrates. They contribute significantly to the designation of the California Floristic Province as a "biodiversity hotspot" (Myers et al., 2000). Some of the key species and the interactions that structure these communities are described below.

Trees

The oaks themselves literally and functionally define the structure of oak savanna, and are best described as the foundation species in these ecosystems. They influence the composition of the understory vegetation, and most of the animal species in these systems depend on the resources that oaks provide, directly or indirectly.

California oak savannas primarily contain oak trees belonging to five different species, two deciduous, one semi-deciduous, and two evergreen. As described above, while there can be overlap in these species distributions, and they may co-occur within stands, many oak savannas in California are dominated by one tree species. Thus we describe here the key tree species and unique attributes of the community in which it predominates, and follow with discussion of some of the common herbaceous plant and the animal species that may be found across many of these savanna habitats.

Blue oak (*Quercus douglasii* Hook. & Arn.) is a winter-deciduous, California endemic species that occupies dry slopes and foothills bordering interior valley grasslands (Fig. 2). Individual blue oaks are small- to medium-sized trees (to 20 m in height) with waxy, bluish-gray leaves (Fig. 3). The density of trees in blue oak savannas ranges from wide spacing with larger trees to more closely packed small trees (Allen-Diaz et al., 1999). In both woodland and savanna settings, blue oak can be the only overstory species present over large areas. However, other tree species present in these habitats can include foothill pine (*Pinus sabiniana*), California buckeye (*Aesculus californica*), valley oak, interior live oak, and coast live oak (Pavlik et al., 1991; Sawyer et al., 2008). This species is the most abundant and widespread of California's oaks, covering nearly 1.3 million ha (Table 1).

Valley oak (*Q. lobata* Née) is another winter-deciduous, California endemic, and is among the largest and longest lived of the North American oaks. Trees are large (up to 32 m in height), with massive spreading limbs and leaves with deep, blunt lobes (Pavlik et al., 1991; Allen-Diaz et al., 1999) (Fig. 4). It occurs in savannas along valley bottoms, foothills, and riparian areas and can co-occur with coast live oak, interior live oak, or blue oak (Pavlik et al., 1991; Sawyer et al., 2008). The distribution of valley oak appears as a discontinuous ring around the Central Valley (Fig. 2). It is far less abundant than blue oak, with an estimated extent of approximately 35,000 ha (Table 1).

Engelmann oak (*Q. engelmannii* Greene) is described as semi-evergreen or semi-deciduous, because it generally retains its leaves until they are replaced in the spring by new foliage (Pavlik et al., 1991). The trees are medium-sized, rarely reaching 18 m in maturity, with thick, muted blue-green leaves. Also known as mesa oak, this species is most abundant on the western foothills and mesas of the Peninsular Ranges; in savanna and woodland settings there it co-occurs with coast live oak. It has been described as ecologically homologous to blue oak in the north (Holland and Keil, 1995). Engelmann oak has the narrowest geographic range of the savanna oaks in California, extending just over 8000 ha (Table 1, Fig. 2). The present Engelmann oaks in the savannas of southern California occur as relict populations, having been relatively widespread in the past (Pavlik et al., 1991).

Fig. 3 Blue oak (*Q. douglasii*) on north facing slope with foothill pine (*P. sabiniana*) and coastal sage scrub. Santa Barbara County. Photograph by C. Tyler.

Table 1 Distribution and extent of foothill oak woodlands and savanna in California. Based on data from Gaman and Firman, 2008.

Dominant species	Hectares (ha)	# oaks (1–10' dbh) per ha	# oaks (> 10' dbh) per ha	General distribution
Blue oak <i>Quercus douglasii</i>	1,289,076	152	9	Interior foothills of the Coast Ranges and Central Valley
Valley oak <i>Q. lobata</i>	34,770	81	7	Interior valleys, foothills, and riparian zones, Santa Monica Mountains north to Oregon
Engelman oak <i>Q. engelmannii</i>	8,246	10	11	Peninsular Ranges, mainly San Diego and Riverside Counties
Coast live oak <i>Q. agrifolia</i>	376,734	251	21	Coastal plain, valleys, and foothills of the Central Coast Ranges, Transvers Ranges, and Peninsular Ranges
Interior live oak <i>Q. wislizeni</i> var. <i>wislizeni</i>	351,976	333	10	Foothill to lower montane zones surrounding the Central Valley, and in southern ranges from upper Sacramento Valley to northern Baja peninsula

**Fig. 4** Valley oak (*Q. lobata*). Photograph by C. Tyler.

Coast live oak (*Q. agrifolia* Née) is evergreen, with dark green, tough leaves, which are convex and have spiny margins. When one is within 50 miles of the coast, both the dark color of the foliage and the dense hemispherical canopy distinguishes this species from the other savanna trees even from a distance. It is one of the largest savanna trees reaching heights of 25 m, but also often has very wide spreading limbs (Fig. 5), up to 40 m wide (Hickman, 1993), with complex branching architecture (Fig. 6). This species is the only oak that flourishes along the coast (from Mendocino County south into Baja California) (Fig. 2), and it can form monospecific stands there, from scattered savanna trees to dense woodland (Pavlik et al., 1991). Further inland, it may co-occur with valley oak and Engelman oak, as well as bay laurel (*Umbellularia californica*), madrone (*Arbutus menziesii*) and toyon (*Heteromeles arbutifolia*). In drier sites, it is associated with blue oak and foothill pine (Holland and Keil, 1995). Coast live oak is the second most widely distributed savanna oak with nearly 377,000 ha (Table 1).

Interior live oak (*Q. wislizeni* A. DC.) can occur in savannas, most often in the northern part of its range, where it is frequently mixed with blue oak and foothill pine (Fig. 2; Allen-Diaz et al., 1999). It is one of the two evergreen oak species found in savannas and, like coast live oak, its leaves are dark green and tough, but they are distinctly flat rather than convex (Pavlik et al., 1991;

Fig. 5 Coast live oak (*Q. agrifolia*). Note that tree breadth exceeds the height. Nonnative annual grasses, especially *Bromus diandrus* in the foreground. Photograph by P. Slaughter.

Fig. 6 Under the canopy of the coast live oak (*Q. agrifolia*) shown in Fig. 5, illustrating the complex branching architecture. Photograph by C. Tyler.

Allen-Diaz et al., 2007). However, hybridization with coast live oak and the scrub oak *Q. parvula* Greene in the lower elevation of the northern Coast Range can produce individuals with intermediate characteristics (Nixon, 2002). In the southern part of the state, it rarely attains the full height of a tree and instead forms part of shrubby chaparral communities. Interior live oak is widely distributed with over 350,000 ha within California (Table 1).

Herbaceous Plants

The understory in oak savannas is typically made up of herbaceous species that are shared with neighboring grasslands, although shrubs may also be present as well as poison oak (*Toxicodendron diversilobum* (Torr. & A. Gray) Greene). Nonnative winter annual grasses and forbs frequently dominate the herbaceous community, particularly species with European or Mediterranean origins (Allen-Diaz et al., 1999). Dominant, exotic grasses include soft chess (*Bromus hordeaceus* L.), rip-gut brome (*B. diandrus* Roth), compact brome (*B. madritensis* L.), wild oats (*Avena barbata* Pott ex Link and *Avena fatua* L.), annual fescue (*Festuca myuros* L.), and foxtail (*Hordeum murinum* L.). These species are pervasive across most savanna communities and along with other annual grasses, likely arrived with Spanish colonists 250 years ago (Bartolome et al., 2007; Hendry, 1931). More recent arrivals include medusa head (*Elymus caput-medusae* L.) and barbed goatgrass (*Aegilops triuncialis* L.). Common forbs, introduced during the same period as the dominant annual grasses, include annual stork's-bills (*Erodium* spp.), mustards (*Brassica* sp. and *Hirschfeldia incana*), and introduced clovers (*Trifolium* spp.) (Hendry, 1931). The deep-rooted summer-annual yellow starthistle (*Centaurea solstitialis* L.) is also widespread in savannas, and is a more recent arrival. Other nonnative thistles, such as italian thistle (*Carduus pycnocephalus* L.) and milk thistle (*Silybum marianum* (L.) Gaertn.), are often located at or near the canopy drip line of the oak trees (Marañón and Bartolome, 1994; Tyler et al., 2007; Stahlheber et al., 2015).

Native herbaceous species are much more variable in their distribution and cover across savannas and grasslands. At six different well-studied grassland sites, native species made up 28–73% of the cover (Bartolome et al., 2007). Perennial bunchgrasses such as purple needle-grass (*Stipa pulchra* Hitchc.) (Fig. 7) are more common on coastal terrace savannas, becoming rarer in interior habitats. Other perennial grasses include prairie Junegrass (*Koeleria macrantha* (Ledeb.) Schult.), squirreltail grass (*Elymus elymoides* (Raf.) Swezey), blue wild rye (*Elymus glaucus* Buckley), pine bluegrass (*Poa secunda* J. Presl) and California brome (*Bromus carinatus* Hook. & Arn.). Some of these native grasses can be found in association with the oak canopy and appear to benefit from the cooler, more fertile microhabitat in the savanna understory (Stahlheber and D'Antonio, 2014; Stahlheber et al., 2015).

The canopy is also strong influence on the diverse community of native herbaceous forbs (Stahlheber et al., 2015). Fiesta flower (*Pholistoma auritum* (Lindl.) Lilja), hoary bowlesia (*Bowlesia incana* Ruiz & Pav.), common bedstraw (*Galium aparine* L.) and miner's lettuce (*Claytonia perfoliata* Donn ex Willd.) are associated with the understory of deciduous and evergreen oaks in savannas (Parker and Muller, 1982; Marañón and Bartolome, 1993; Stahlheber et al., 2015). Native forbs common in the open spaces between the trees and in larger grassland patches are also diverse, including California poppy (*Eschscholzia californica* Cham.) (Fig. 8), lupines (*Lupinus* spp.), lotuses/trefoils (*Acmispon* spp.), owl's clover (*Castilleja exserta*) (Fig. 9), goldfields (*Lasthenia* spp.) and clovers (*Trifolium* spp.) just to name a small selection.

Not much is known about the composition of the herbaceous plant community prior to the arrival of Europeans and their novel plants. Surveys and reports from explorers and missionaries in California before 1900 offer some insight into the general kinds of plants present in these habitats, but are too sparse to offer much to our understanding of species composition. Although many ecologists have historically assumed *S. pulchra* was a dominant member of the herbaceous community (Clements, 1934; Holland and Keil, 1995), there is little direct evidence for complete dominance of perennial bunchgrasses throughout the state (Hamilton, 1997; Bartolome et al., 2007). Instead, close examination of these early accounts and study of soil phytoliths (microscopic particles of biogenic silica that have different characteristics for grasses and broadleaf plants) suggests that much of California's Central Valley was not dominated by perennial grasses but rather by forbs (Minnich, 2008; Fick and Evett, 2018). Therefore, like the Central Valley grasslands, more interior oak savannas also likely had a substantial component of annual and perennial forb species.

Animals: Invertebrates

Thousands of invertebrate species are associated with California's oak woodland habitats, including an estimated 5000 arthropod species—mainly insects (Swiecki et al., 1997). Some depend on and affect oaks directly and thus are found associated with the savanna trees (described below), while others are more common in the open grassland. Included in the latter group are

Fig. 7 Native perennial bunchgrass, *Stipa pulchra*. Photograph by C. Tyler.

Fig. 8 California poppies (*Eschscholzia californica*) in the grassland between oaks. Photograph by C. Tyler.

Fig. 9 Native annuals, including purple owls' clover, *Castilleja exserta*. Photograph by C. Tyler.

grasshoppers, which are important herbivores impacting both herbaceous annual and perennial plants. In California there are over 200 species of grasshoppers, and more than half are native to the state and found nowhere else (Schiffman, 2007).

One of the noticeable, yet relatively harmless, groups of insects found on oaks is the gall-inducing cynipid wasps. There are over 200 species of cynipid gall wasps, which specialize on either the white oak or black oak group of California oaks (Russo, 2006). Complex communities of insects are associated with the galls themselves, including predators, parasites, competitors and mutualists, attracted to the developing wasp larvae (Russo, 2006) (Fig. 10).

Fig. 10 Valley oak gall, induced by the California gall wasp, *Andricus quercuscalifornicus*. Photograph by C. Tyler.

Other species directly dependent on the oaks are the California oak worm (*Phryganidia californica*), which is the larval stage of the California oak moth, and filbert weevil (moth larva, *Curculio* sp.) and filbertworm (beetle larva, *Cydia latiferreana*), which are the most common invertebrate consumers of acorns. In addition to the impacts these herbivores have on the vegetation, they also are important food sources for vertebrate consumers.

Animals: Vertebrates

Reptiles and amphibians benefit from shelter provided by leaf litter, downed wood or hollows in oak trunks, as well as abundant food sources—especially insects and small mammals (Block and Morrison, 1998; Tietje and Vreeland, 1997; Tietje et al., 1997). Lizards and snakes are important predators in oak communities and species represented include skinks (*Plestiodon* spp.), western fence lizard (*Sceloporus occidentalis*), California legless lizard (*Sceloporus occidentalis*), alligator lizards (*Elgeria* spp.), racers (*Coluber* spp.), common king-snake (*Lampropeltis getula*), gopher snake (*Pituophis catenifer*) and western rattlesnake (*Crotalus oreganus*). Amphibian abundance and diversity vary considerably with site conditions; most species depend on moist microsites under downed logs, litter, riparian elements or vernal pools (Block and Morrison, 1998). Among the most common amphibian species are slender salamanders (*Batrachoseps* spp.), ensatinas (*Ensatina* spp), and chorus frogs (*Pseudacris* spp.) (Tietje and Vreeland, 1997; Block and Morrison, 1998).

Birds are the most diverse vertebrate group in these habitats, with over 100 species represented. Some rely on acorns for food, including the acorn woodpecker (*Melanerpes formicivorus*), western scrub-jay (*Aphelocoma californica*), and the yellow-billed magpie (*Pica nuttalli*). Others, such as phainopepla (*Phainopepla nitens*) and western bluebird (*Sialia mexicana*), rely on food sources associated with oaks, such as mistletoe fruits or insects. Raptors such as red-tailed hawk (*Buteo jamaicensis*), red-shouldered hawk (*Buteo lineatus*), Cooper's hawk (*Accipiter cooperii*), great horned owl (*Bubo virginianus*) and golden eagle (*Aquila chrysaetos*), though not restricted to oak habitats, nest in these woodlands and can play a major role in the community trophic structure as predators on small mammal populations (Tietje et al., 1997). Turkey vultures (*Cathartes aura*) are an ever-present and important scavenger, consuming carrion in these habitats.

Mammals that are found in oak savanna habitats include consumers of insects, seeds, or herbs such as bats, brush rabbit (*Sylvilagus bachmani*), California ground squirrel (*Otospermophilus beecheyi*), Botta's pocket gopher (*Thomomys bottae*) and other rodents. The distribution and abundance of rodent species vary with microhabitat such as shrub and downed wood cover: for example, dusky-footed woodrats (*Neotoma fuscipes*) are more abundant where there is shrub cover, whereas a sparsely vegetated ground cover is associated with higher numbers of deer mice (*Peromyscus* spp.) (Tietje and Vreeland, 1997). Large mammals here include omnivores and browsers such as American black bear (*Ursus americanus*) and mule deer (*Odocoileus hemionus*), as well as carnivores such as cougar (*Puma concolor*), bobcat (*Lynx rufus*), American badger (*Taxidea taxus*), coyote (*Canis latrans*), gray fox (*Urocyon cinereoargenteus*), and long-tailed weasel (*Mustela frenata*).

Factors Affecting Species Distributions and Community Composition

Climate

Climate imposes one of the broadest controls on the distribution of grasslands and co-occurring woody vegetation in California. The ranges of precipitation and temperature experienced by the savanna and grasslands described here would fall into the climate zone, described by Whittaker (1975), "in which either grassland, or one of the types dominated by woody plants may form the

prevailing vegetation". In addition, climate exerts finer scale influences on the dynamic patterns at the grass-tree boundaries, as well as the seasonal and annual variation in productivity, seed production, and biodiversity.

Interannual variation in precipitation and the timing of the first germinating rain in fall can cause major changes in the composition of the herbaceous plant community in oak savannas (Slade et al., 1975; Bartolome, 1979). Shifts between "grass years" and "forb years" are common in response to environmental conditions, including lag times in the response of wildflowers (Pitt and Heady, 1978; Reeve Morghan et al., 2007). Increased rainfall tends to favor the exotic annual grasses, often at the expense of native plant species richness and invertebrate food webs (Suttle et al., 2007).

In addition to the effects of climate on the distribution and range of individual oak species (see section on Distribution), climate also has effects on oak populations. Rainfall can have profound implications for oak seedling emergence and initial survival, although established seedlings are less likely to be killed by drought (Griffin, 1971; Borchert et al., 1989; Tyler et al., 2008; Mahall et al., 2009; Davis et al., 2019). Competition for soil water between oak seedlings, nonnative annual grasses and established adults can constrain early growth of oak trees (Gordon and Rice, 2000), especially in the driest parts of their range.

Weather is a primary factor driving masting for oak species, including those in California (Koenig et al., 2016, 2017). In particular, rainfall and temperatures during the spring and summer are key drivers of acorn production, especially for evergreen species (Koenig et al., 2016). Studies in valley oak have suggested considerable local adaptation of populations to climate, which could have important implications for the future of oak savannas as the regional climate changes (Sork et al., 2010, 2016).

Over the past 50 years the major trends in changing climate in these systems have been: an increase in mean annual temperature and minimum nighttime temperatures, and increased interannual variation in temperature and rainfall (Christy et al., 2006; LaDochy et al., 2007). Global climate models are consistent in predicting that California will continue to warm over the next century (Cayan et al., 2008). As described above, climate influences oak savanna and grasslands in multiple ways, from seed production, seedling establishment and survival, and community species composition. It has been suggested that grasslands, which are dominated by annual species, may experience changes in the relative abundance of native compared to nonnative grass species due to predicted changes in the timing and duration of rain events (Suttle et al., 2007; Eviner, 2016). The establishment and ultimately the overall ranges of savanna oak species has been predicted to decline with warming climate (Kueppers et al., 2005; McLaughlin and Zavaleta, 2012; Davis et al., 2016). Thus climate will continue to play a major role in determining the distribution and make-up of California's oak savanna and grassland ecosystems.

Soil Type

Oak savannas are most often found on noncalic Mollisols typical of grasslands, with medium-heavy texture and moderate organic matter. As mentioned previously, valley oak savannas are commonly located on deep, fertile valley bottom and riparian soils, whereas blue oak savannas occupy sandier, rockier soils typical of slopes. The parent materials underlying these savannas have a variety of origins, chemistries and physical properties. In general, blue, valley and coast live oak occupy sites with sandstones and shales, along with granitic parent materials north and east of the Central Valley (Allen-Diaz et al., 1999). Interior live oak savannas on the other hand frequently are found on mafic, metamorphic and deep igneous parent materials (Allen-Diaz et al., 1999).

The presence of the oak canopy in savannas creates patchiness in soil properties, as the oak trees can create "islands of fertility" beneath their canopy. Soil organic matter, cation-exchange capacity, inorganic nitrogen and nitrogen turnover rates are often higher below the canopy (Parker and Muller, 1982; Jackson et al., 1990; Frost and Edinger, 1991; Dahlgren et al., 1997; Herman et al., 2003; Stahlheber et al., 2015), likely contributing to the effects of oaks on productivity and understory composition.

Tree-Grass Interactions

The oak canopy exerts a strong influence on the productivity and community composition in the understory relative to neighboring open grassland. Interactions between the understory and blue oak trees range from facilitative to competitive, leading to trees that have higher or lower productivity beneath them relative to the surrounding grassland (Callaway et al., 1991). Climate, precipitation, and/or root distribution likely all contribute to whether a tree will positively or negatively affect understory production (Callaway et al., 1991; McClaran and Bartolome, 1989; Frost et al., 1997). Legacy effects of oak trees are persistent, although more so in terms of composition than productivity. Both evergreen and deciduous oak canopies favor growth and establishment of ripgut brome (*B. diandrus*) thus it is often abundant in the understory whereas other grasses (*B. hordeaceus* and *Avena* spp) are favored in open spaces (Parker and Muller, 1982; Marañón and Bartolome, 1993; Rice and Nagy, 2000; Stahlheber et al., 2015). These dominant, productive populations of ripgut brome can persist more than 30 years following the death of the tree; therefore legacy effects of a former canopy may be important sources of patchiness in composition of savanna herbaceous communities (Holland, 1980; Bartolome et al., 1994; Stahlheber et al., 2015).

Plant-Animal Interactions

Oaks Providing Food and Habitat for Animals

Many of the animals residing in oak savanna rely on the food or shelter that oaks provide (California Department of Fish and Wildlife, 2008). Acorns are a carbohydrate-rich food resource for many species. This resource varies considerably from year to year,

especially in white and red oak species like blue oak, valley oak and coast live oak, whose acorns mature in 1 year (Koenig and Knops, 2013; Koenig et al., 1994). Oak mast seeding behavior has been found to drive population dynamics of animals dependent on them and throughout the food webs (Koenig and Knops, 2005; Koenig et al., 2009; Ostfeld et al., 2006).

Other resources provided by the oaks include leaves, twigs, sap, leaf litter, and a complex physical structure including canopy, shaded and open branches, cavities, bark, and standing, dead or downed logs. These serve as either food or shelter to a variety of animal species.

Oak savannas, which are by definition diverse in structure—with elements of both woodlands and grasslands—sustain diverse communities that include species generally found in one or the other habitat, but here overlap in their distributions.

Mutualist Seed-Dispersers

Though oaks do not require that their acorns are dispersed or buried by animals, this “service” provided by birds or small mammals greatly increases the likelihood that acorns will successfully germinate and become established seedlings. Most acorns that drop under the adult oak trees are eaten, and those that are left on the soil surface are killed by desiccation or heat stress. Acorns that are shallowly buried have a higher probability of producing emergent seedlings (Borchert et al., 1989; Tietje et al., 1991). While some acorns may be buried naturally (e.g., by falling into deep leaf litter), acorn-hoarding animals play an important role in getting the acorns to microsites that promote their survival and germination. One of the most important acorn “planters” is the western scrub-jay (*Aphelocoma californica*), which may scatter-hoard, or “plant”, up to 5000 acorns in a season but only recover and consume half (Carmen, 1988), leaving thousands of buried acorns across the landscape. Other acorn-caching or hoarding animals include yellow-billed magpie (*Pica nuttalli*) and California ground squirrel (*Otospermophilus beecheyi*).

Ecosystem Engineers

Ecosystem engineers are organisms that impact the availability of resources to other species by causing physical changes to the environment (Jones et al., 1994). Residing in oak savannas and woodland are several animal species that play this role (Schiffman, 2007). Botta’s pocket gopher (*Thomomys bottae*) function as “soil engineers” because their burrowing causes high rates of soil turnover and their tailings cause disturbances that, among other impacts, mediate competition between annual and perennial plant species (Hobbs and Mooney, 1995; Stromberg and Griffin, 1996; Seabloom and Richards, 2003). California (or Beechey) ground squirrel (*Otospermophilus beecheyi*) similarly impacts the soil environment with their extensive burrowing. Badgers (*Taxidea taxus*) are impressive soil excavators, tunneling sparse but extensive underground burrows, which may be as far as 3 m below the surface with up to 10 m of tunnels. Nonnative wild pigs (*Sus scrofa*) are an important agent of soil disturbance in many oak woodlands and grasslands, but, unlike other animals that may foster higher biodiversity by creating heterogeneity in the soil environments, pig activities are usually associated with increases in nonnative plant species that recover from pig disturbance faster than native species (Tierney and Cushman, 2006). All of these ecosystem engineers influence the composition of soil biota, herbaceous vegetation, and potentially the establishment of oaks by moving or removing acorns.

Animals Contributing to the Oak Regeneration Problem

As has been reported for other oak woodlands around the world, California’s oak savannas are generally composed of large, old adults with few individuals in the smaller, younger classes, raising concerns that there is an oak regeneration problem, that is, that natural recruitment of the oaks may be insufficient to balance adult mortality. Among the factors often cited as limiting oak recruitment are acorn and seedling predation, and herbivory of established seedlings and saplings (Tyler et al., 2006). Predation by small mammals, including mice, gophers, voles, and ground squirrels has been shown to be a major source of acorn and seedling mortality for most California tree oaks (Griffin, 1971, 1980; Borchert et al., 1989; Callaway, 1992; Tyler et al., 2008).

Herbivory and browsing of seedlings and saplings also strongly limits oak establishment in some sites. Leaf defoliation by grasshoppers, root damage by pocket gophers and voles, and bark girdling by mice have all been reported to cause mortality or severe damage to established oak seedlings and saplings (Griffin, 1976; McCreary and Tecklin, 1994; Bernhardt and Swiecki, 1997; Tyler et al., 2008). In addition, browsing by deer has been noted to significantly reduce growth of oak saplings and limits their transition to larger size-classes (White, 1966; Griffin, 1971; Davis et al., 2011, 2019). The commonly-observed associations of natural oak seedlings with shrub canopies (Callaway and D’Antonio, 1991; Callaway, 1992) are likely a result of protection provided by shrubs from herbivory and browsing by mammals.

Human Impacts

Early Uses, Tree-Cutting, and Firewood Harvesting

Oaks served an important function to California’s indigenous cultures by providing sustenance; acorns were a staple in the diet of most native American tribes residing among the oaks woodlands and savannas in the region (Rossi, 1980; Keator, 1998). Because of this dependence on an important food source, it is unlikely that tree-cutting would have been prevalent in that time period (Rossi, 1980).

Following European exploration and settlement, oaks were harvested for several uses, including fuel for heating and cooking, timbers for mine supports or fencing, and for the production of charcoal. Since oaks were less desirable compared to pines in producing strong, straight lumber, historically there were no large-scale forestry operations initiated in California oak savannas and woodlands (Rossi, 1980).

In the present day, cutting of oak trees for firewood still occurs, but at a relatively low rate. A 4-year, state-wide survey of firewood harvesting in California found that there was annual harvest of approximately 2400 ha, representing <0.1% of the total hardwood rangeland (Standiford et al., 1996). This harvesting took place primarily in just two counties, and in most locations growth surpassed harvest, in terms of oak tree volume. The authors concluded that firewood harvest of oaks was not a dominant factor impacting these woodlands.

Fire

Lightning ignitions in the coastal and lower-elevation foothill habitats occupied by oak savannas and woodlands are rare, among the lowest rates in the southwestern United States (Keeley, 2002; Davis et al., 2016). Convective lightning storms are relatively rare in the summer, when fuels are dry and in the winter, fuel moisture is high enough to resist ignition (Keeley, 2002). Human and lightning ignitions are difficult to separate in the paleoecological record, but the occurrence of large, catastrophic fires does suggest some naturally-ignited fire (Keeley, 2002; Mensing et al., 1999). Today, humans are the source of almost all ignitions in these habitats (Keeley, 2002; Davis et al., 2016).

The southern and central Coast ranges of California have been settled since at least the late Pleistocene/early Holocene (Erlandson, 1997). By the late Holocene, even without engaging in agriculture, the complex hunter-gatherer societies of indigenous Californians had some of the highest population densities in North America (Lightfoot and Parrish, 2009). They managed the wild plant communities they inhabited with fire, and given the density of human settlement in oak savanna habitats, it is likely that Native American fire had significant impacts on these communities (Keeley, 2002; Anderson, 2005; Mensing, 2006). Indeed, the expansion of oak habitat throughout California following the last glaciation coincided with the first appearance of people, so environmental modification may have been central to their success along with a changing climate (Mensing, 2005). Burning (as often as every 1–3 years) would have enhanced the abundance of hunted game, the production of seeds from desirable herbaceous plants, as well as increased the abundance of corms and bulbs (Keeley, 2002; Lightfoot and Parrish, 2009; Bartolome et al., 2007). Van de Water and Safford (2011) collected available literature on Pre-European fire return intervals in California vegetation and estimated a mean return interval of 12 years for oak woodlands and savannas with a range from 5 to 45 years. Current fire return intervals in oak-dominated habitats in the Los Padres National Forest range from 13 to 103 years, with a mean of approximately 41 years (an average departure of almost 30 years from the likely historical fire regime) (USFS FRID database; <http://www.fs.fed.us/r5/rs/clearinghouse/r5gis/frid/>).

As shown in coastal oak habitats, wildfire can mediate transitions between oak woodland/savanna communities, open grassland and shrubland phases by reducing establishment of woody plants into grassland or shrubland (Callaway and Davis, 1993). Seedlings and saplings of oaks can be killed by high-intensity fires, slowing recruitment of trees (Mensing, 1998; Swiecki and Bernhardt, 2002; Bartolome et al., 2002). On the other hand, adult oak trees are generally resilient to the effects of fire; their thick bark protects them from cambial damage and coast live oak, blue oak and valley oak often vigorously resprout from the crown and interior live oak can resprout from the base (Fry, 2008; Haggerty, 1994). Prescribed fire has only rarely been used in these habitats, partly due to the fact that >80% of oak savannas and woodlands are privately owned, and many have been, and still are, used for livestock grazing (Huntsinger et al., 2010).

Changing climate may significantly alter the role of fire in structuring these systems. As a result of warming temperatures it is likely that oak savannas and grasslands will experience new fire regimes and longer fire seasons. More frequent fire may increase the relative cover of grassland and decrease abundance of oaks. Such a change would have cascading impacts through the plant and animal communities.

Livestock Grazing

Most of the large (>200 acres) properties with oak woodland and savanna are used for livestock grazing, and the owners tend to live on their properties, participate in voluntary land conservation programs and are often concerned about the effects of oak on forage (Huntsinger et al., 2010). Oak thinning has been common in grazed landscapes, often for “rangeland improvement” (Frost et al., 1997). However, more landowners have come to value multifunctionality and diverse ecosystem services from their oak properties, viewing them as important “working landscapes” (Huntsinger et al., 2010). Along with this change in perspective is an interest in using grazing as a land management tool, both to reduce fire hazard for human dwellings and maintain a diverse herbaceous plant community (Huntsinger et al., 2010; Stahlheber and D’Antonio, 2013; Bartolome et al., 2014).

Continuous grazing at high stocking rates is frequently implicated in the invasion of California grasslands by nonnative annual species and the loss of perennial grasses (Bartolome et al., 2007). Large animals reduce dominance of tall grasses, break up litter layers and favor short, broad-leaved plants (Díaz et al., 2007). Grazing used as a conservation or management tool is most often applied by rotating cattle through smaller pastures during the wet/grass-growing season (November to May). A recent meta-analysis

of grazing studies in California grasslands (some including oak savanna habitat) found that across the state, grazing tended to increase the richness and abundance of exotic forbs (Stahlheber and D'Antonio, 2013). There were also positive impacts on native forbs, especially in arid, inland sites compared to those in the Coast Ranges (Stahlheber and D'Antonio, 2013). The response of native grasses appeared to be much more variable.

Oak understory and open grassland habitats do not necessarily respond the same way to grazing. Trees can change the behavior of grazers, causing them to congregate in shade or seek out the more nutritious forage present in the understory (Senft et al., 1985; Frost et al., 1991; Treydte et al., 2010). Most studies of grazing in oak woodland or savanna habitats have not separated understory and intertree locations when considering the effects on native and exotic plant populations. A recent study that did compare understory to open grassland locations found that in open sites outside the canopy (> 5 m from the edge) of valley oaks, cattle grazing breaks up litter layers formed by *B. diandrus* and other annual grasses, increasing species richness and facilitating native species (Stahlheber et al., 2017). By contrast, the understory of coast live oak and valley oak had higher species richness and cover of native species when grazing was removed (Stahlheber et al., 2017). These results suggest that implementing grazing to benefit native species will have highly variable outcomes in oak savanna depending on tree density, livestock behavior and the species already present in understory and open habitats.

Grazing can also have effects on attributes beyond the herbaceous plant community, including oak regeneration, soil attributes and the abundance of animals. Cattle may reduce the success of oak recruitment, however, small mammals can have much larger effects (Tyler et al., 2008; Davis et al., 2019). These small mammals such as gophers and ground squirrels can themselves be affected by cattle grazing (Stromberg and Griffin, 1996, but see Fehmi et al., 2005). Most studies have also found relatively muted effects of grazing on oak understory soils outside of a small increase in bulk density and some changes in soil phosphorus availability (Dahlgren et al., 1997; Tate et al., 2004; Stahlheber et al., 2017).

Current Threats

Regeneration Problem

As described above, in California's oak woodlands and especially in oak savannas, researchers have observed low recruitment rates, even as early as the 1990s (Sudworth, 1908; Jepson, 1910). Stands of trees that are dominated by old adults raises concerns about potential population decline, or an "oak regeneration problem". Field surveys of California oak species, including those important to savanna ecosystems, indicate that in many sites there are very low numbers of oak seedlings and young saplings present (Bolsinger, 1988; Tyler et al., 2006; Allen-Diaz et al., 2007). The degree to which oak populations are declining, stable, or increasing appears to vary among species and to vary regionally. For example, live oaks may be increasing in some regions, blue oak populations appear to be regenerating adequately in many locations, but valley oak populations in Central California and Engelmann oak in Southern California appear to be declining (Tyler et al., 2006).

There are many physical and biotic factors that can limit establishment of oaks in savanna habitats. These include: low rainfall in some years, acorn diseases, acorn predation, herbivory of established seedlings and saplings, competition between oak seedlings and nonnative annual grasses for water, soil compaction by cattle, and low adult tree population density. Any one of these factors can prevent the establishment of seedlings and the subsequent transition to sapling and tree (Tyler et al., 2006).

Predicted changes in climate, including increased temperatures and increased variability in rainfall may well impact oak recruitment in multiple ways. As described previously, climate affects acorn production: spring temperature and humidity impact pollen production and dispersal. Higher temperatures at ground level may reduce acorn and seedling survival. Reduced availability of water-requiring vegetation may also drive higher rates of browsing and herbivory on existing saplings. The few studies that have examined potential impacts of climate change on oaks support the prediction that oak establishment will become more limited with warming conditions (Kueppers et al., 2005; McLaughlin and Zavaleta, 2012), thereby exacerbating regeneration problems already reported in some savanna habitats.

Habitat Loss and Degradation Due to Land-Use Conversion

Arguably the most significant threat to California oak savannas is the outright clearing of oak trees and conversion of the land for residential development and agriculture. Although oaks themselves provide multiple benefits to both humans and other organisms as a natural resource, as of the mid-1980s between 3 and 5 million of California's original 10–12 million acres of oak woodland habitats had been lost largely due to rangeland clearing, agricultural conversion and urban development (Bolsinger, 1988). Most lowland oak woodland conversion to cropland and orchards occurred in the latter half of the 19th century, primarily in valleys and floodplains that could support growth of crops, such as open sites around the Central Valley. By the 1880s, much of the state's grassland had been plowed, and 75% of the area within the Central Valley had been converted to production. Even hillsides that today do not appear plowed probably once were during this period. Stromberg and Griffin (1996) found that cultivation has large impacts on present day composition; native perennial bunchgrasses in particular appear to be mostly restricted to unplowed sites.

In the last quarter of the 20th century another wave of agricultural conversion took place, with the burgeoning wine industry in California; vineyard acreage expanded by nearly 300% just between 1976 and 2010 (Davis et al., 2016).

Residential development in both suburban and rural areas has heavily impacted oak woodlands and savannas since the 1950s. Even where development has occurred on relatively large lots—those between 5 and 20 acres—the habitat becomes fragmented by roads and fencing, and environmentally degraded due to changes in understory vegetation, disruptions to animal communities, and impacts to air and water quality. Such impacts are likely to continue as demands for new housing accompany projected increases in the state's population.

Abstract

Grasslands, woodlands, and associated communities comprise a biologically diverse ecoregion in western Oregon, Washington, and British Columbia. These habitats contrast conspicuously with the coniferous forests that largely surround them and were historically strongly shaped by a pronounced summer-dry Mediterranean climate together with frequent fires set by Native Americans. Agricultural development, urbanization, and forest encroachment have resulted in the loss over 90% of these habitat types in most areas. Remnants are mostly small and highly fragmented. Conservation efforts focus on restoring native species diversity, managing invasive species, and enlarging acreages to enhance ecological resilience.

Introduction

Conifer forests largely dominate the vegetation of the middle latitudes along the Pacific Coast of North America. Yet within portions of this region, substantial areas of nonforested vegetation occur. These areas have many affinities in life form and climate with grassland, savanna, and woodland biomes elsewhere in the world, and are generally regarded as falling within a single ecoregion (Floberg et al., 2004, EPA website). In this article, we follow Floberg et al.'s (2004) delineation and refer to these habitats as comprising the Willamette Valley-Puget Trough-Georgia Basin (WPG) ecoregion. They lie west of the Cascade Mountains in northwestern Oregon, western Washington, and southwestern British Columbia, and extend nearly 800 km, from about 44–50°N latitude. A disproportionate amount of the region's biodiversity is associated with these vegetation types, and the connections to human influences—past, present, and future—are a source of significant ecological and conservation interest. Botanical nomenclature follows Hitchcock and Cronquist (2018).

History and Physical Setting

Historical Extent and Distribution

Grasslands, savannas, and open woodlands are closely related habitat types that overlap and intergrade. Historically, they were most commonly found in the lowlands west of the Cascade Mountains and east of the Coast Ranges and Olympic Mountains, within the area known as the Willamette Valley-Puget Trough-Georgia Basin (WPG) ecoregion (Floberg et al., 2004; Fig. 1). Different terms are sometimes used within the ecoregion to refer to these communities. Grasslands are widely referred to as “prairies” throughout much

Fig. 1 Map of the Willamette Valley-Puget Sound-Georgia Basin ecoregion in western Washington, Oregon, and British Columbia.

of the range, although the term “balds” is frequently used in the San Juan archipelago (Chappell, 2006) and “meadows” in southwestern British Columbia. The overall range of these habitats is fairly well tracked by occurrences of the native oak, *Quercus garryana* var. *garryana*, a dominant species of both savannas and woodlands. This species is known as Oregon white oak or Garry oak, the latter name being applied in British Columbia to describe the suite of grasslands and woodlands of high conservation value—the “Garry oak ecosystem” (GOERT, n.d.). Its range extends somewhat beyond that of the WPG, reaching south into California and crossing the Cascades slightly in southern Washington.

The historical extent of these habitat types at the time of Euro-American settlement (ca. 1850) has been documented from early land surveys, as well as inference based on occurrences of grassland soils. They were most extensive in the Willamette Valley, with over 400,000 ha of prairie, 200,000 ha of savanna, and 250,000 ha of woodland (Christy and Alverson, 2011). These habitats were less extensive in the lowlands of western Washington and British Columbia, and detailed estimates of the historical acreages of the

different habitat types are less certain. Chappell et al. (2001, 2003) estimated grasslands in presettlement times occupied about 73,000 ha in western Washington, with the majority occurring south of Puget Sound. Mixed oak-conifer savannas and woodlands were often associated with these prairies, but their historical extent in Washington is less certain. In British Columbia, prairies and associated oak habitats were most extensive on southeastern Vancouver Island, the adjacent Gulf Islands, and in the lower Fraser River Valley. Approximately 12,000 ha of presettlement prairies, savannas, and balds have been mapped (Lea, 2006), but this does not include areas of historically fire-influenced woodland, or balds that lacked an extensive oak component.

Paleoecology

Across most of the region, the present-day vegetation only developed in the Holocene following the climatic and environmental changes accompanying the end of the Ice Age. Numerous fossil pollen records from sediment cores throughout the WPG ecoregion generally show species with xerophytic affinities, including *Quercus*, reaching their maximum abundance in the Hypsithermal, 5–8000 years ago, suggesting that prairie and savanna habitats were also at their maximum extent during this time (Whitlock, 1992; Leopold and Boyd, 1999; Leopold et al., 2016). Walsh et al. (2008) and others also describe fossil charcoal records during the Hypsithermal that suggest frequent low to moderate severity fires, which may in part reflect human ignitions of these habitats.

Various origins for individual elements of the flora can be posited. *Quercus garryana* itself belongs to a lineage with a long history in the fossil record in western North America that extends back to the Miocene species *Quercus prelobata* (Retallack, 2004). In some cases, important herbaceous elements in the vegetation belong to lineages or genera endemic to the Pacific Northwest or western North America (e.g., *Camassia*), while other important taxa are widespread across the northern hemisphere (e.g., *Deschampsia cespitosa*).

Climate

The present-day climate in prairie and savanna areas throughout the WPG ecoregion shows a Mediterranean-type pattern of seasonal precipitation, with warm, dry summers and mild, wet winters (Table 1). Unlike most temperate grasslands, where most of the precipitation occurs in late spring and early summer, 75–90% of annual precipitation typically occurs from October through April. However, total precipitation varies by a factor of two to three times across the WPG ecoregion. At the north end of the region, precipitation in the San Juan and Gulf Islands averages only 40–65 cm due to their location within the rain shadow of the Olympic Mountains of western Washington. Farther south, average annual precipitation is considerably greater, reaching 130 cm in southern Puget Sound and 100–120 cm in the Willamette Valley. The Willamette Valley and southern Washington sites are significantly wetter than most temperate grasslands elsewhere in the world, which typically average 50–90 cm annually (UC-Berkeley website). Overall, temperatures tend to be more moderate in the WPG ecoregion than most other grasslands due to the oceanic influence. Winter temperatures are relatively mild for the latitude; frosts are common but hard freezes less so, and winter snowfall is uncommon and rarely persists for long. Summer temperatures are similarly moderate, with average August maxima ranging from 20°C in the north to 28°C in the Willamette Valley.

Soils

Soil parent materials generally are of late-Pleistocene and Holocene age throughout the WPG ecoregion, although they vary considerably in origin. The northern half of the region (Thurston County, Washington northward) was impacted by the most recent extent of the continental ice sheets. As a consequence, soils are often derived from glacial deposits, particularly outwash, which are often

Table 1 Average annual and summer (June–August) precipitation, maximum August temperature, and minimum January temperature for stations in prairie habitat types in the WPG ecoregion from the southern Willamette Valley (Eugene) to southwestern British Columbia (Victoria).

Comparable data from grassland habitats in the Great Plains are listed for comparison.
<https://www.usclimatedata.com/climate/>.

excessively drained mixtures of sand, silt, and gravel. Bedrock outcrops occur frequently in the San Juan and Gulf Islands, where grasslands often are associated with shallow soils on bedrock and on dry coastal bluffs.

South of the limit of the continental glaciation, some prairie areas have developed on older deposits, but most are found on fine sediments dropped by the massive late-glacial Missoula floods, which scoured materials from western Montana, Idaho, and eastern Washington. These sediments were deposited across the entire Willamette Valley below an elevation of about 120 m (O'Connor et al., 2001).

Hydrology

Prairie and savanna vegetation may be found in association with a wide range of hydrologic conditions. While most remnants of these habitats on the landscape today occur in droughty, well-drained uplands, extensive prairies historically occurred on deeper, more mesic soils that were rapidly converted to agriculture by early Euro-American settlers (Boyd, 1999; Lea, 2006). Wet prairies also were frequent, especially along rivers and on poorly-drained substrates, but have been virtually extirpated by hydrological alterations, agriculture practices, and encroachment of invasive species. In many portions of the WPG ecoregion, prairies and savannas are associated with azonal soils characteristic of sites—both wet and dry—where conifers (particularly Douglas-fir—*Pseudotsuga menziesii*) are poorly adapted or less competitive.

Biota

Community Types

Grasslands, savannas, and woodlands in the WPG ecoregion often transition gradually from one type to another rather than changing abruptly in structure and species composition. While grasslands are readily recognized by a dominance of herbaceous species and only a minor presence of shrubs or an occasional tree, savannas and woodlands are less clearly distinguished from each other, being defined primarily on the basis of tree density and canopy cover. Savannas are generally considered to have a canopy < 25–30%, with woodlands defined by a denser canopy between 30% and 70%, above which they usually are considered to be forest. Some authors have further distinguished between open and closed oak woodlands (Altman, 2011).

Grasslands

Grass-forb dominated communities vary along gradients of seasonal hydrology, substrate composition, and soil depth and texture. Prairies on deep soils with adequate drainage were historically among the most extensive community types, but were also among the first areas to be converted to agriculture. As a result, examples of these habitat types in good condition are scarce today throughout the region. Regardless of the total precipitation received, the herbaceous vegetation dominating these habitats tends to be of low to moderate stature (generally < 50 cm tall). This is unlike most other temperate grasslands, where areas with higher annual precipitation generally support bunchgrasses and forbs that may reach 1.5–2 m or more in height. The short stature may result from the pronounced summer drought limiting growth for most species, particularly in July and August.

Numerous herbaceous-dominated plant associations have been described across the ecoregion, although it is generally recognized that historically, many others likely occurred as well. In Washington, Chappell (2004) described 10 grassland associations. In British Columbia, few native grasslands remain, and descriptions of Garry Oak Ecosystem community types largely include plant associations that include *Quercus garryana* as an important component (Erickson, 2002). The Oregon Natural Areas Program has described several Willamette Valley grassland ecosystems along gradients of soil depth and winter hydrology (Oregon Natural Areas Program, 2015).

The species composition of these plant associations varies considerably across the ecoregion. Soil composition, depth and fertility, together with seasonal moisture stress are likely some of the more important factors that contribute to this variability. Appendix A lists the more common native species (i.e., those present in > 70% of sites in at least one ecoregional sector) that are frequently encountered in the upland grassland/savanna habitat types in major sectors of the ecoregion. These data are drawn from the remnants of these habitats that still survive, which are often small and thus may not be entirely representative of the historical occurrences of the species.

In general, the flowers of diverse forbs are conspicuous in the spring (April–May), with bulbous species, particularly *Camassia quamash* or *C. leichtlinii*, often abundant (Fig. 2). Considerably fewer forbs flower in summer or autumn, likely reflecting the pronounced summer drought. Native annual grasses are minimally represented in the flora. Although annual forbs are inconspicuous in today's prairies, this may be due to the lack of fire over the last 150 years (Dunwiddie et al., 2014). Frequent burning consumes accumulated litter and moss, a conspicuous groundcover in many regional prairies. This produces larger gaps among the perennial plants where annuals can flourish. In addition, burning tends to increase forb abundance over the native grasses (Fig. 3). In contrast to the diversity of forbs, remarkably few species of native bunchgrass are dominant. Roemer's fescue (*Festuca roemerii*) occurs throughout the WPG ecoregion, and is thought to have historically been the primary native grass in many dry, upland prairies in the Willamette Valley and southern Washington (Titus et al., 1996). Red fescue (native forms of *Festuca rubra*) tends to be the more common bunchgrass farther north in the San Juan and Gulf Islands,

Fig. 2 Abundant *Camassia quamash* in a South Puget Sound prairie, with *Quercus garryana* in the background. Photography by P. Dunwiddie.

Fig. 3 Postfire flowering in a forb-rich bald in the San Juan Islands dominated by *Ranunculus occidentalis*, *Castilleja hispida*, and *Camassia leichtlinii* spp. *suksdorfii*. Photography by P. Green

with very few other grasses (*Danthonia californica*, *Elymus glaucus*, *Elymus trachycaulis*, *Koeleria macrantha*, and *Bromus carinatus*) conspicuous in some areas.

Due to many decades of livestock grazing and other disturbance, the prairie remnants that still persist generally are significantly degraded. Many native species almost certainly have been extirpated from most sites. For example, in a study of 15 of the largest prairie remnants in South Puget Sound, 40% of the native plant species occurred in only 1 or 2 prairies (Dunwiddie et al., 2006). Sites also have been greatly altered by the introduction of a large number of nonnative plant species. The same study of South Puget Sound prairies found 39% of the species are nonnative. A similar 36% were recorded in grasslands in the San Juan Islands (Dunwiddie, 2018). These figures are likely representative of habitat degradation in other sectors of the WPG ecoregion as well.

Wet prairies are a distinctive variant most commonly found in the southern half of the ecoregion, but historically present to a smaller extent in the northern half as well. Wet prairies occur where the water table is at or near the soil surface, at least in the winter, creating conditions for hydrophytic vegetation. *Deschampsia cespitosa* is the dominant grass in many wet prairies in Oregon, along with species of sedge (*Carex*) and other graminoids. Vast acreages of wet prairies have been drained and converted to pasture and cropland, or have been overrun by *Phalaris arundinacea* and other nonnative grasses.

Fig. 4 Prairie and *Quercus garryana*–*Quercus kelloggii* savanna in the southern Willamette Valley. Photography by E. Alverson.

Savannas and Woodlands

Savannas consist of an understory comprised largely of prairie grasses and forbs with an open tree canopy. The arboreal component generally is comprised of Oregon white oak, Douglas-fir, or other fire-tolerant conifers which vary regionally, but include *Calocedrus decurrens*, *Pinus ponderosa*, or *Pinus contorta*. Other drought-tolerant trees that occur in savannas include *Quercus kelloggii* (southern Willamette Valley only), *Fraxinus latifolia*, *Arbutus menziesii*, and *Juniperus maritima* (San Juan and Gulf Islands only). To a large degree, the herbaceous understory of savannas historically was similar to prairies, but with a greater representation of shrubs and shade tolerant woodland species (Fig. 4).

Woodlands are often found near prairies and savannas, and may in part have developed in response to interactions between topography, soils, and fire frequency. Prairie fires tend to become more patchy and die out as they enter the shadier, cooler, and moister conditions under trees, thereby greatly reducing the burn frequency to perhaps every 10–30 years. This would have inhibited survival of regenerating conifers while favoring oaks and shrubs such as *Corylus cornuta* var. *californica*, *Symphoricarpos albus*, *Rosa* spp., and (in the Willamette Valley) *Toxicodendron diversilobum*, all of which resprout after fire. These taller woody species would have shaded out many grasses and forbs, further reducing the fine fuels that carried frequent fires in more open vegetation.

In the absence of fire since settlement, savannas and woodlands have largely succeeded to forest, and considerable uncertainty exists about their understory composition in pre-settlement times when they were being frequently burned. Today, remnant open-grown oak trees surrounded by younger forest-grown trees are an indicator of a former savanna that has converted to forest. In some areas where fire frequencies may have been higher, oak forests often include many multitemmed trees. These likely were denser stands of stump-sprouted oak brush at the time of settlement which were released to develop into forest in the absence of fire. Because the oaks are less shade tolerant, slower growing, and smaller statured than Douglas-fir trees, in many areas oaks have been overtopped by conifers and are dying out beneath a Douglas-fir forest canopy.

Oak woodlands and forests are still relatively extensive in the Willamette Valley. However, in many cases they occupy sites that were savanna at the time of Euro-American settlement, and which developed as a result of a reduction in fire frequency (Fig. 5). Such sites now have a depauperate native herbaceous flora and may not be representative of their historical composition or structure. Patches of oak woodland are part of the landscape mosaic in western Washington and British Columbia, in some cases persisting on sites where saturated soils in the winter preclude establishment of Douglas-fir.

Oak-dominated plant associations or community types have been variously described across the WPG ecoregion. In Oregon, two oak-dominated savanna types and three woodland types were described by Buechling et al. (2008), whereas in Washington, Chappell (2004) described three savanna types dominated by *Quercus garryana*, *Pseudotsuga menziesii*, and *Pinus ponderosa*, respectively, and an additional 11 oak-dominated woodland types. At the northern end of the range of *Quercus garryana*, a finer community taxonomy has been described in British Columbia, where Erickson (2002) examined the relationship between 26 oak-dominated community types and various environmental variables. However, no single system for characterizing these associations has emerged that can be readily applied throughout the ecoregion.

Biogeography and Floristics

Overall, about 716 native vascular plant taxa have been documented from grasslands, savannas, and woodland habitats in the WPG ecoregion. 554 of these show high or moderate fidelity to at least one of these three habitats. The remaining 162 taxa are more typical of other habitats, such as conifer forests, riparian forests, or wetlands. Many species are widespread across the ecoregion; of the high and moderate fidelity taxa, 53% are documented from most of the WPG, although very few are dominant throughout

Fig. 5 Late summer view of a Willamette Valley oak woodland showing an open grown presettlement oak surrounded by dense younger oaks, which likely established due to a reduction in fire frequency. The red foliage belongs to the liana form of *Toxicodendron diversilobum*. Photography by E. Alverson.

(see [Appendix A](#)). Nevertheless, there is considerable variability in the composition of similar communities in different areas. For example, 25% of the taxa are documented from only one portion of the ecoregion.

The high and moderate fidelity species are represented by 68 vascular plant families and 259 genera. The top species-rich families (with the number of native taxa represented) are Asteraceae (76), Poaceae (44), Fabaceae (39), Plantaginaceae (21), Apiaceae (20), and Saxifragaceae (20). The most species-rich genera are *Trifolium* (14 taxa), *Carex* (13 taxa), *Lupinus* (11 taxa), and *Lomatium* (9 taxa). Bulbous monocots, formerly assigned to Liliaceae but now divided among Amaryllidaceae, Asparagaceae, Liliaceae, and Melanthiaceae are particularly conspicuous in the flora, and are represented by 29 taxa.

Twenty-nine species, subspecies, or varieties of vascular plants are endemic or nearly endemic to the WPG ecoregion and occur exclusively or predominantly in oak or prairie habitats ([Table 2](#)). Many of these are species of conservation concern due to their rarity throughout the ecoregion. Of the 27 endemics that have been ranked according to NatureServe's methodology, 20 (74%) are considered to be at risk, with a Global Status of G3 or lower. Six taxa (22%) are ranked G1, which is defined as "critically imperiled." Listing of some of these species under federal and state/province endangered species laws has helped to focus conservation attention and reduced the likelihood of them becoming extinct. For example, *Castilleja levisecta* had been extirpated in Oregon and reduced to about 12 sites globally before it was federally listed as threatened in the United States in 1997. Since then, it has been established in over 40 sites throughout its historical range, with some populations exceeding 50,000 flowering plants (Dunwiddie, unpublished data).

Like *Quercus garryana*, many of the prairie and woodland species in the WPG ecoregion have the center of their geographic distribution in northern California and southwestern Oregon, and thus represent a northern extension of the Californian flora. However, some taxa are more widely distributed east of the Cascades and may have arrived via long-distance dispersal. A few examples these eastern disjuncts include *Iris missouriensis*, *Lomatium grayi*, *Shepherdia canadensis*, and *Balsamorhiza hookeri*. Others, such as *Bistorta bistortoides*, *Carex aurea*, *Oxytropis campestris* var. *spicata*, *Micranthes oregana*, and *Vaccinium cespitosum*, are more typically found at high elevations in the mountains in the Pacific Northwest, and may be persistent relics from late-glacial times.

Fauna

The grassland and woodland habitats of the WPG ecoregion do not support the diversity of large ungulates characteristic of many other similar temperate biomes. Black-tailed deer and Roosevelt elk are the main large herbivores in these habitats. Historically, the Columbian white-tailed deer was present in the Willamette Valley, though it was extirpated following Euro-American settlement. Historically, gray wolves were present, as well as grizzly bears in the Willamette Valley; cougars, black bears, and coyotes are predators that are still present ([Vesely and Rosenberg, 2010](#)). Various smaller mammals are present in many areas, including rodents

^aNear-endemic.

(mice, voles, woodrats, and introduced rats), squirrels, rabbits, and pocket gophers. Among these species, several are of particular conservation concern. The western gray squirrel (*Sciurus griseus*) is common in Oregon but is extremely rare in western Washington, where it is limited to a few mixed oak-conifer woodlands near Olympia. The gray-tailed vole (*Microtus canicaudus*) and camas pocket gopher, (*Thomomys bulbivorus*) are endemic to Willamette Valley prairies and savannas, and several subspecies of the Mazama pocket gopher (*Thomomys mazama*) found in WPG grasslands are considered rare, while two appear to be extinct.

Forty-nine species of birds are highly associated with prairie and oak habitats of the WPG ecoregion (Altman, 2011). Twenty-one have exhibited notable declines in range and/or population size, and three have been extirpated as breeding populations—burrowing owl (*Speotyto cunicularia*), Lewis's woodpecker (*Melanerpes lewis*), and Say's phoebe (*Sayornis saya*). Two subspecies are endemic to the habitats—the streaked horned lark (*Eremophila alpestris strigata*) and Oregon vesper sparrow (*Pooecetes gramineus affinis*), and a third, the slender-billed white-breasted nuthatch (*Sitta carolinensis aculeata*) is a near-endemic.

Overall, the invertebrate fauna of these habitats is poorly known. Butterflies are among the best-studied groups, with approximately 81 taxa currently known to occur in the WPG ecoregion (Appendix B). Sixteen species are of conservation concern, thirteen of these are endemic or near-endemic to the ecoregion (Table 3), and four are the focus of considerable conservation efforts, including Taylor's checkerspot (*Euphydryas editha taylori*), mardon skipper (*Polites mardon*), island marble (*Euchloe ausonides insulanus*), and Fender's blue (*Icaricia icarioides fenderi*) (Schultz et al., 2011). Interest in the native bees and other pollinators of these habitats in the ecoregion is increasing, but data summarizing species, abundance, and distribution is lacking. Additional research documenting the conservation and habitat management needs of native invertebrates would be beneficial.

Ecological Processes

Grasslands in the Pacific Northwest frequently occur on substrates that are too droughty for trees to readily establish. However, moisture stress is not sufficient to maintain these open, herbaceous-dominated ecosystems in most areas. Conditions suitable for tree establishment frequently arise, and once started, woody species from the surrounding forests—most commonly

^aNear-endemic.

Douglas-fir, oaks, and various shrubs—are able to thrive and often grow more rapidly than in the forest. As with most temperate grasslands, fire historically played a major role in limiting tree encroachment. In the WPG ecoregion, fires were largely ignited by indigenous tribes for at least the last several millennia and perhaps much longer (Whitlock, 1992; Storm and Shebitz, 2006; Weiser and Lepofsky, 2009). Such burning limited encroachment of woody vegetation, thereby maintaining the prairies as openings in the extensive conifer forests of the region despite the high precipitation in many areas that favors growth of trees. Frequent prairie fires enhanced the diversity and growth of numerous plants that provided Native Americans with important food and medicinal resources. Storm and Shebitz (2006) report that 83% of 153 species in southwestern Washington prairies had cultural uses, with 35% of these used for food. Camas bulbs were especially valued, and along with salmon, served as a primary dietary staple for most tribes in the region. Most ethnographic evidence suggests that prairies were ignited in the late summer or fall throughout the ecoregion (Boyd, 1999; Storm and Shebitz, 2006). Storm and Shebitz suggested that prairies were ignited every 1–2 years, but the patchiness of vegetation and fuels resulting from such frequent burning likely produced a longer fire rotation for any particular patch of prairie, perhaps burning every 3–5 years or longer.

The large-scale harvesting of roots, rhizomes, and bulbs such as *Camassia*, *Lomatium*, *Fritillaria*, and *Pteridium* would have resulted in significant soil disturbance and creation of gaps in the prairie vegetation matrix. Similarly, burrowing animals likely were historically more abundant and widespread, further adding to soil disturbance. These activities, together with the regular ignition of fires, would have combined to significantly shape the vegetation composition, as well as influence ecological processes such as pollination, pest impacts, and nutrient cycling. Today's prairies may differ in important ways from their historical antecedents due to alteration or absence of these processes.

Savannas and woodlands, which often occur immediately adjacent to prairies, were also strongly influenced by fire. Fires ignited in the grasslands would regularly burn into the surrounding forests, killing smaller trees and shrubs and helping to maintain the more open character of the savannas and woodlands. As in the prairies, burning released nutrients and stimulated growth that enhanced berry production and vigor of plants with edible leaves, shoots, roots, and rhizomes. Where oaks were present, fall burns also cleared brush and litter, facilitating acorn collection by indigenous people (Turner, 1999).

Fire is a common element limiting ecological succession and maintaining vegetation in a seral state in many temperate grasslands worldwide. However, the grasslands of the WPG ecoregion differ from those of the Great Plains and many other regions in their lack of large herds of grazing ungulates. Although black-tailed deer and occasionally elk were present in many areas, they did not occur in the numbers that would have impacted the ecology of these systems to the extent seen in similar grasslands elsewhere. Thus, it is not surprising that trees and other woody vegetation have rapidly and extensively increased in these communities, frequently transforming them into different vegetation types since Euro-American settlers brought an end to the fires set by Native Americans.

Threats

Remnants of prairie, savanna, and oak woodland can be found throughout most of the WPG ecoregion. However, throughout the region these habitats have declined by 90–99% from three main causes: conversion for agriculture, urban development, and succession to forest in the absence of fire (Noss et al., 1995; Crawford and Hall, 1997; Lea, 2006; Christy and Alverson, 2011; Dunwiddie and Bakker, 2011).

In the 1.2 million ha Oregon portion of the WPG ecoregion, remaining oak-dominated vegetation occupies ca. 44,000 ha, though most is in a highly altered state (Alverson, 2011). The same study found a similar amount (ca. 42,000 ha) of

grassland types. Although higher quality prairies were not distinguished, they probably do not exceed 1–2% of the historical extent. Of the original extent of prairie in the Willamette Valley, ca. 70% is now utilized for agriculture, 15% has converted to conifer forest through ecological succession, and 10% has been lost to urbanization and other development. In savanna habitats, 45% is utilized for agriculture, 35% is forest, and 10% has been developed (Hulse et al., 2002). Nearly half of the remaining acreage of these habitats occurs in parcels exceeding 25 ha, but only about 9% occurs on lands under some type of conservation ownership. In South Puget Sound, Crawford and Hall (1997) reported that of the 60,000 ha with grassland soils, only 3% were dominated by native prairie species. Present day extent of savannas and oak woodlands is not as well documented, but the Spanaway-Lakewood area of Pierce County, which historically supported the most extensive savannas, has largely been urbanized.

In the northern Puget Sound region, prairies are restricted to small remnants, field corners, and roadsides, but are still important refuges for endangered prairie species such as golden paintbrush. Herbaceous balds, particularly in the San Juan and Gulf Islands, have been less affected by habitat loss due to their unsuitability for cultivation, although many have been negatively impacted by grazing, resulting in loss of native species diversity and invasion of nonnative plant species. Some of the highest quality remnants are located on small islands that were too small to be subject to regular grazing by domestic livestock (Dunwiddie, 2018). Studies by Lea (2006) in British Columbia show similarly extensive losses, with ca. 1600 ha (less than 5%) of these ecosystems remaining, largely limited to only a few small fragmented remnants. Overall, urbanization and forest encroachment likely remain the primary threats, as nearly all areas that were potentially important for agriculture have already been converted.

Invasive nonnative species have had a major impact in reducing ecological function and native species abundance. Nonnative grasses, mostly Eurasian in origin, predominate in many remnants due to historical agricultural conversion and grazing. Native forbs have also declined, many being desired forage for livestock, or because of an inability to compete with nonnative herbaceous species in disturbed areas. While not all nonnative plant species are invasive, Dennehy et al. (2011) listed over 100 species that are currently or potentially invasive in prairie and oak habitats. Important or noteworthy nonnative grasses include *Agrostis capillaris*, *Arrhenatherum elatius*, *Brachypodium sylvaticum*, *Schedonorus arundinaceus*, and *Phalaris arundinacea* (in wet prairies). Important nonnative forbs include *Centaurea* spp., *Daucus carota*, *Geranium lucidum*, *Hieracium pilosella*, *Hypericum perforatum*, *Hypochaeris radicata*, *Leucanthemum vulgare*, *Potentilla recta*, and *Senecio jacobaea*. Prominent nonnative woody species, which have colonized prairie and oak remnants and altered ecological function in major ways, include *Cytisus* spp. (largely *C. scoparius*), *Crataegus monogyna*, *Daphne laureola*, *Pyrus communis*, *Prunus avium*, *Rosa* spp., and *Rubus bifrons* (= *R. armeniacus*). Most of these species are native to temperate regions of Eurasia, where they have evolved under the influence of agriculture and grazing of domestic livestock, and thus have been able to respond better than native species to grazing and agricultural management in WPG prairies, savannas, and oak woodlands. And while some invasive nonnative plants can be fairly readily managed by fire (e.g., *Cytisus scoparius*), many respond positively to burning (Nuckols et al., 2011).

Anticipating how prairie and oak habitats will respond to climate change is challenging. Climatic models for the Willamette Valley project hotter and likely drier conditions (Shafer and Bartlein, 2015), which might be expected to favor oaks over conifers, but may also favor grassland habitats over forests (Michalak et al., 2017). Yet considerable uncertainties remain not only regarding the extent and rate of predicted environmental changes, but also how numerous other factors will change in response. Fire frequency and severity, CO₂ fertilization, species interactions, introduction of invasive taxa and new pathogens, increased habitat fragmentation, and human responses, are just a few critical factors that are likely to have not only significant direct effects, but complex and often unpredictable interactions as well. Extant prairies and savannas represent remnants of habitats that reached their peak extent during the Hypsithermal, when the climate was warmer and drier than today, and have survived for millennia in a dynamic world. Whether these systems and the species that comprise them have the ecological, genetic, and physiological capacity to adapt to a rapidly-changing environment and landscape remains uncertain.

Conservation and Research

There are few large acreages of predominantly native grassland remaining in the WPG ecoregion. The main exceptions are on a military base in South Puget Sound (Joint Base Lewis-McChord), where nearly 5000 ha of prairies remain, including several over 1000 ha. In most areas, prairies that once extended for thousands of hectares have been reduced to small, highly fragmented remnants. Most of these remnants are less than a few hundred hectares, and often much smaller. Many of these have already been protected from development by conservation organizations and government agencies, so there are relatively few opportunities to preserve significant acreages of native prairie. Instead, future acquisitions of land for prairie conservation are likely to focus on undeveloped farmland (Dunwiddie and Bakker, 2011; Sinclair et al., 2006). Although native species may be largely absent in such areas, the presence of prairie soils offer important conservation opportunities by providing locations where native prairie species can be planted, beginning the long process of recreating the complex associations of plants, pollinators, and ecological processes that comprise viable prairie communities.

In native prairie remnants that have been protected, conservation efforts are largely directed in two main areas—removing and managing invasive non-native plants, and reestablishing and introducing native species to increase diversity and enhance ecological resilience of the prairie communities. Managers use a variety of tools to achieve these restoration objectives, such as setting fires and applying selective herbicides to treat invasive plants and create favorable conditions in which to sow seed of native species

(Stanley et al., 2011a,b). Because many of these sites are small and isolated, managers are constrained in terms of the ecological functionality that can be restored. For example, prescribed fires in prairie remnants burn much smaller areas than historical fires would have consumed, or cannot be ignited when these historical fires were set due to air quality or safety concerns. It may be difficult or impossible to sustain populations of some nesting birds that require territories larger than a preserve. Butterflies that rely on recolonizing locally extirpated populations by dispersal of individuals from nearby sites may be difficult to maintain on isolated sites.

As a result of these constraints, managers of natural areas that include remnants of prairie, savanna, and woodland habitats have come to recognize that most sites require frequent and intensive intervention, and cannot simply be left alone to let nature take its course. To retain rare species, minimize the impact of invasive species, and sustain healthy populations of a large diversity of species, active restoration is required. The science of ecological restoration is still evolving, with much that remains to be learned about how to effectively and efficiently maintain and restore these systems and their biota. Academic and agency scientists often collaborate with land managers across the region to research questions that advance conservation objectives in two main areas. First, much research is directed toward understanding the biology and ecology of individual species, particularly rare species that are primarily found in the WPG habitats. Preventing the extinction of species such as golden paintbrush, Taylor's checkerspot, or streaked horned larks relies on recognizing key vulnerabilities in their life cycle, understanding what comprises optimal habitat, and helping managers integrate this information into conservation actions. Second, extensive research also is focused on the habitat management process itself—how best to reduce invasive species, establish native species, and maintain healthy communities over the long term. The process of creating and maintaining prairies and woodlands in a landscape that is rapidly urbanizing, within a changing sea of newly arriving, often invasive species, and in a climate that is presenting new and still uncertain challenges, will require continued new insights, creativity, and perseverance by WPG researchers and conservationists.

Future

In recent decades, the prairie and savanna habitats of the WPG ecoregion have become the focus of a remarkable network of conservation programs. The inherent synchrony of natural and human systems that have come into play to create these vibrant ecosystems has inspired citizens, practitioners, and researchers to apply a hands-on approach to conserving, managing, and restoring these ecosystems. While efforts to date have led to many successes, questions remain as to how successfully managers can mitigate the numerous threats prairies and savannas and their biota face in the coming decades. Extreme habitat loss is further eroded by fragmentation, reduced habitat quality, invasive species, and loss of appropriate fire regimes. Despite thousands of hectares of remnant prairies and savannas being under conservation management, this acreage still represents only a small fraction of the historical extent.

Today's prairie and savanna species are inexorably altered from their condition when the first Euro-American explorers and settlers were arriving a mere two centuries ago. Numerous species of nonnative plants, animals, and fungi have become permanent residents. Meanwhile, it is unclear how well the resulting novel ecosystems will be able to sustain the remaining native biodiversity. It is possible that current levels of extinction debt, together with extensive and rapid changes in future climate and habitat, may doom many species unless conservationists are able to greatly expand available habitat, enhance connectivity, and facilitate dispersal of species to more favorable environments (Dunwiddie et al., 2009; Dunwiddie and Rogers, 2017). While hotter temperatures and increased moisture stress in the future may expand prairie and savanna habitats by reducing tree density in transitional sites, it is also possible that the species that are capable of moving into newly created openings will largely be nonnative unless proactive steps are taken to assist in the establishment of less vagile native species.

As the community of conservation practitioners moves to take on these challenges, new perspectives will be valuable to help improve prospects for success. Developing restoration implementation strategies that use the most effective treatments and maximize the likelihood of restoration success through staged restoration or other hedging methods may be key (Bakker et al., 2018). Ultimately, in an ecoregion that has been so heavily modified, ecological restoration in the Pacific Northwest may depend on the degree to which it can be closely integrated with cultural restoration—that is, sustaining native ecosystems as a social and cultural goal (Dunwiddie and Bakker, 2011). Working collaboratively to incorporate the values of native cultures—such as reviving camas harvesting and use of native plant materials—may be an especially integral part of future conservation success.

Appendix A

Common vascular plants of Pacific Northwest prairies. Species recorded in >70% of prairie/oak sites for four sectors within the WPG ecoregion. Percent frequency of species in each sector was calculated based on comprehensive species lists for multiple sites. The total number of sites used to calculate percentages in each sector are: South Willamette Valley (20), South Puget Sound (15), San Juan Islands (62), and Vancouver Island and adjacent Gulf Islands of southwestern BC (31). x = Species present but documented from <70% of inventoried sites in that subregion.

Acknowledgments

We are grateful to the many researchers that have generously contributed data used in the summaries of plants and butterflies found across the ecoregion. In addition to our own plant species lists for many sites, we also drew on datasets made available by Joe Bennett, Patrick Lilley, Jenny McCune, and James and Kristen Miskelly. Information and lists for butterflies were contributed by James Miskelly, Jonathan Pelham, Ann Potter, Robert M. Pyle, and Dana Ross.

Abstract

The sagebrush (*Artemisia* spp.) biome extends throughout arid and semi-arid environments in the western U.S., stretching northward into southwestern Canada and eastward to the western Great Plains. The sagebrush biome primarily consists of sagebrush-steppe, with relatively abundant perennial bunchgrasses, and sagebrush shrublands that are generally more desert-like with sparser herbaceous cover. Big sagebrush (*A. tridentata*) is the most widely distributed species, but other sagebrush species are found throughout the biome, some in relatively distinct environments. Sagebrush communities range from almost pure sagebrush to a diverse mix of shrubs, grasses, and forbs, often with complex biological soil crust communities. Sagebrush ecosystems provide habitat for hundreds of species of conservation concern, including sagebrush-obligate wildlife such as the greater sage-grouse (*Centrocercus urophasianus*), a widely distributed species that is declining across most of its range, primarily due to deteriorating habitat quality. Roughly ~45% of the historical area of sagebrush steppe/shrublands has been lost due to human activities, including: over-grazing by livestock, clearing to enhance rangeland forage, energy development, roads, cropland conversion; altered fire regimes driven by invasive, fire-prone, annual plant species; and expansion of woodlands caused by land use and climate variability. Climate change will likely have significant future impacts on sagebrush ecosystems. Conservation of sagebrush ecosystems is critical for the myriad species supported, ecological services provided, and the iconic character of western U.S. landscapes, and will likely require enhanced efforts to restore and protect sagebrush habitat from detrimental land uses and wildfire. Scientific research can provide a better understanding of how interactions among various stressors affect sagebrush communities, and how to best manage and prioritize sagebrush habitats for conservation.

What Are Sagebrush Steppe and Sagebrush Shrublands?

“Sagebrush” are woody shrub or subshrub species contained within the genus *Artemisia*, mostly within the subgenus *Tridentatae*, and all of which are endemic to North America. There have been numerous taxonomic revisions, but approximately 12 sagebrush species in the subgenus *Tridentatae* are currently recognized (depending on the taxonomic authority), with a similar number of subordinate taxa; however, several allied species are also generally considered “sagebrush” (McArthur and Sanderson, 1999; Shultz, 2009, 2012; Garcia et al., 2011). Most sagebrush species are evergreen, and the leaves persist on the plant through the winter for several years, permitting winter photosynthesis; however, many species produce both ephemeral and persistent leaves which can vary in size and shape (Shultz, 2012). Sagebrush do not have showy flowers common to other members of the Asteraceae family to which they belong, but they are known for their distinctive, aromatic “sage” odor derived from volatile compounds, especially in the glands of their leaves, which helps to reduce herbivory by insects and grazing animals. However, sagebrush are a valuable and nutritious food source for many insect and wildlife species, especially in the fall and winter when leaf concentrations of volatile compounds are lower (Rosentreter, 2005).

Sagebrush ecosystems are commonly classified into either a shrub-steppe type or a shrubland type, with sagebrush-steppe generally characterized by the potential for co-dominance of perennial bunchgrasses, and sagebrush shrublands typically defined as more desert-like and containing a dominant shrub overstory with relatively sparse cover of grasses and forbs. The dominant species vary greatly among specific sagebrush community types (Table 1) depending on environmental setting and disturbance history, but sagebrush steppe communities are typically dominated by one of three subspecies of big sagebrush (*A. tridentata*), including basin big sagebrush (*A. t. tridentata*), Wyoming big sagebrush (*A. t. wyomingensis*), and mountain big sagebrush (*A. t. vaseyana*). Other common sagebrush ecosystems are dominated by “low” or “dwarf” forms of the species, often growing on shallow, rocky, or poorly drained soils (West and Young, 2000), including low sagebrush (*A. arbuscula*) and black sagebrush (*A. nova*). Other sagebrush species (e.g., *A. pygmaea*, *A. rothrockii*) grow in more limited habitats, often reflecting dry locations and unique soil environments (McArthur, 2000).

Table 1 Some of the most common and dominant sagebrush species and subspecies of the sagebrush steppe and sagebrush shrublands, with summaries of their distribution, key characteristics, and environmental settings.

Species/subspecies	Common name	Description and environmental settings
<i>Artemisia arbuscula</i>	Low (little) sagebrush	This widespread, short-statured sagebrush species occurs in a wide variety of habitats, and the four recognized subspecies often exist in unique soils conditions among big sagebrush communities, including poorly drained clayey soils in alkali basins and on dry, high-elevation, windy ridges. Elevations range from < 1000 m to over 3500 m, and annual precipitation ranges from 20 cm to > 50 cm
<i>A. cana</i>	Silver sagebrush	The three recognized subspecies of this low sagebrush occupy distinct habitats, ranging from areas with relatively high moisture/precipitation areas (e.g., near streams rivers, snowmelt) often at high elevations (up to 3300 m), to lower elevation basins and playas, and eastward into the grasslands of the Great Plains
<i>A. nova</i>	Black sagebrush	A short-statured sagebrush species typically located in warmer, drier sites with shallow, rocky, and often calcareous soils throughout much of the interior mountain west. Annual precipitation ranges from 15 cm to 50 cm; typical elevation is 1200–2400 m
<i>A. rigida</i>	Scabland (rigid) sagebrush	A low-growing sagebrush species found primarily on volcanic, often shallow rocky soils, mostly in the Columbia Basin (Washington and Oregon). Annual precipitation ranges from 20 cm to 40 cm, and elevation 230–2100 m
<i>A. tridentata</i>	Big sagebrush	Most widespread of the sagebrush species (with several recognized subspecies), ranging from Sierra Nevada and Cascade Mts. east to the Great Plains, and from southern Canada to Arizona, New Mexico, and northern Baja Mexico. Big sagebrush is the dominant shrub species in much of the sagebrush steppe and shrublands, and often on the northwestern Great Plains. Big sagebrush taxa are found on a wide variety of soils, with annual precipitation ranging from 20 cm to > 75 cm, and elevations ranging from 600 m to > 3000 m. Three primary subspecies with broad geographical ranges are described below
<i>A. t. ssp. tridentata</i>	Basin big sagebrush	Deep rooted subspecies of big sagebrush found on lower elevation (600–2000 m) sites with deep, fertile soils (loamy to sandy) and annual precipitation 20–40 cm. Plants can exceed 3 m in height, with spreading, irregularly-shaped crowns
<i>A. t. ssp. vaseyana</i>	Mountain big sagebrush	A big sagebrush subspecies commonly found at higher elevations (typically 1000–3200 m) on mountain slopes and meadows, often more mesic and productive than other sagebrush sites; with annual precipitation ~35–45 cm
<i>A. t. ssp. wyomingensis</i>	Wyoming big sagebrush	Common and widespread big sagebrush subspecies that forms extensive communities in the interior western U.S., found on generally well-drained, loamy soils (but shallower than for <i>A. t. ssp. tridentata</i>) across dry sites (18–30 cm precipitation per year) at low- to mid-elevations (800–2200 m)
<i>A. tripartita</i>	Threetip sagebrush	There are two recognized subspecies, one reaching up to 2 m in height and occurring on igneous-derived soils, and a less common low-growing subspecies (< 40 cm in height). The former, more common threetip subspecies is found throughout the sagebrush steppe where annual precipitation is generally 30–40 cm and elevation ranges from 900 m to 2400 m. This is one of the few sagebrush species that resprouts after disturbance, including fire
<i>A. bigelovii</i>	Bigelow sage	A short- to mid-sized sagebrush found primarily in the Colorado Plateau region and the desert grasslands and scrublands of the southwest

Where Are Sagebrush Ecosystems Found?

Sagebrush ecosystems are commonly found throughout the interior western U.S., generally occurring in arid to semi-arid climates, with wide distribution across the plateaus and basins that exist between and surrounding mountain ranges, and often forming the dominant vegetation type over vast landscapes. The sagebrush biome extends from southwestern Canada (British Columbia, Alberta, and Saskatchewan) southward into northern New Mexico and Arizona, and stretches from the eastern slopes of the Sierra Nevada and Cascade Mountains to western North Dakota, South Dakota and Nebraska (Fig. 1). Prior to EuroAmerican settlement, ecosystems with sagebrush taxa as a significant component likely extended over more than 1 million square kilometers (km²) (Beetle, 1960), although estimates vary depending on how sagebrush ecosystems are defined and delineated (Welch and Criddle, 2003). Based on distribution of potential natural vegetation types (Küchler, 1970), sagebrush-steppe habitat (including the wheatgrass-needlegrass steppe of the Wyoming Basin) covers ~450,000 km² and sagebrush shrublands (delineated here as generally coinciding with the Great Basin sagebrush type) cover ~180,000 km² (West and Young, 2000), with hundreds of thousands of

Fig. 1 The distribution of the sagebrush steppe and sagebrush shrubland ecosystems as defined by potential natural vegetation type (Küchler, 1970), and set within the context of a generalized distribution of extant sagebrush ecosystems that are often scattered among other natural community types (e.g., grasslands, woodlands) or human-developed landscapes (e.g., agricultural lands).

additional square kilometers containing scattered sagebrush communities or areas in which sagebrush is an important component but not necessarily dominant (Fig. 1).

Sagebrush communities generally occur where winters are long, with cool to cold temperatures, and summers are hot and dry (McArthur, 2000). Sagebrush community composition and structure vary along broadly-defined bioclimatic gradients, but can also vary abruptly with changes in topography, geology, elevation, and soils that affect growing conditions (e.g., plant-available water). The primary sagebrush taxa generally occur where annual precipitation averages 18–35 cm, usually occupying elevations below woodlands and forests, but above salt-desert shrub communities. However, mountain big sagebrush (*A. t. ssp. vaseyana*) can form extensive communities at higher elevations with generally wetter environments (35–45+ cm precipitation per year) and species such as silver sagebrush (*A. cana*) also occur at higher elevations or in moist habitats near streams, in meadows, or in areas with more persistent snowpack (McArthur, 2000; Miller et al., 2011a,b).

In the western portion of the sagebrush biome, most precipitation arrives as winter snow or rain, summers are hot and dry, and deeper soil water storage favors deep-rooted woody species such as sagebrush. Within these “cold desert” ecoregions, the sagebrush shrubland type is coarsely delineated from sagebrush-steppe by generally occurring south of a climate transition zone in which warmer temperatures and seasonal changes in precipitation limit the abundance and productivity of perennial bunchgrasses (Miller et al., 2011a,b; Chambers et al., 2017). As a result, the Northern Basin and Range, Snake River Plain, Wyoming Basin, and Columbia

Plateau ecoregions generally support shrub-steppe communities, while the Colorado Plateau, Central Basin and Range, and Arizona/New Mexico Plateau generally support sagebrush shrublands with sparser herbaceous cover. The proportion of annual precipitation arriving during warmer months also increases toward the eastern edge of the sagebrush biome, where shrublands converge with prairie grasslands, and silver sagebrush and sand sagebrush (*A. filifolia*) may be co-dominant with grasses, or grass-dominated prairie landscapes contain scattered Wyoming big sagebrush communities, characteristic of much of the northwestern Great Plains. Sagebrush communities are also found throughout the valleys, foothills, and southerly-facing slopes of the western mountain ranges that separate cold desert ecoregions (Chambers et al., 2017).

Ecological Attributes

Structure and Composition

Sagebrush communities can range from almost pure sagebrush, especially on more xeric sites, to a diverse mix of shrubs, grasses, and forbs, especially on more mesic sites. Sagebrush community types classified at the alliance or association level within the International Vegetation Classification system (Reid et al., 2002) are those in which sagebrush species are typically either dominant or co-dominant in the overstory, sometimes with other shrub species, such as bitterbrush (*Purshia tridentata*) or snowberry (*Symphoricarpos* spp.), and often further delineated by prevalent herbaceous species, especially tussock forming “bunchgrasses” that occur in the understory or spaces between shrubs in much of the sagebrush biome. In northern portions of the sagebrush biome and at higher elevations, diagnostic bunchgrasses for classification include species such as bluebunch wheatgrass (*Pseudoroegneria spicata*) or Idaho fescue (*Festuca idahoensis*), while broadly-adapted species and those that tolerate drought conditions, such as Sandberg bluegrass (*Poa secunda*) or bottlebrush squirreltail (*Elymus elymoides*), become more dominant in warmer and drier areas. There is also a transition from cool-season bunchgrasses that dominate much of the sagebrush steppe to increasing presence of warm-season or sod-forming grasses (e.g., *Bouteloua* spp., *Sporobolus* spp.) in sagebrush shrublands in more southerly portions of the biome. In the northwestern Great Plains, needlegrasses (e.g., *Hesperostipa* spp., *Achnatherum* spp.), wheatgrasses (e.g., *Pascopyrum smithii*, *Elymus* spp.), grama grasses (*Bouteloua* spp.), and bluestem species (e.g., *Andropogon gerardii*, *Schizachyrium scoparium*) tend to dominate. At higher elevations, sagebrush species can form understory components of mountain shrub and woodland communities (e.g., *Purshia tridentata*, *Cercocarpus* spp., *Juniperus* spp., *Pinus* spp.), while at lower elevations, sagebrush often interperse with salt-desert shrub communities (e.g., *Atriplex* spp., *Sarcobatus* spp., *Krascheninnikovia lanata*).

The size and dominance of sagebrush plants varies with sagebrush species, environmental setting, and disturbance history. For instance, in the sagebrush steppe, shrub cover varies widely (~10–80%) depending on site conditions and disturbance history (West and Young, 2000). The overstory shrub layer in most sagebrush steppe and shrublands is typically 0.3–1.0 m tall; however, basin big sagebrush can exceed 3 m in height. Understory layers of grasses and forbs are typically <0.4 m tall, and the relative cover and production of herbaceous species varies greatly depending on community type, growing season moisture availability, site conditions and disturbance history. There is often greater density and shorter stature of sagebrush plants on xeric sites where sagebrush can comprise more than 70% of relative plant cover (West and Young, 2000). Biological soil crusts or bare ground may dominate inter-spaces between shrubs, especially within more arid sites where herbaceous species are found mostly under or near shrubs (Miller et al., 2011a,b). Biological soil crusts are considered good indicators of rangeland ecosystem health, and often include complex assemblages of lichens, mosses, cyanobacteria, green algae, and micro-fungi that can protect soil surfaces from erosion, regulate nutrient availability, and provide sites with favorable conditions for germination of native plant species (Belnap et al., 2001).

Biological Diversity Supported by Sagebrush Ecosystems

Sagebrush ecosystems provide habitat for over 350 plant and animal species of conservation concern (Wisdom et al., 2005), including several sagebrush-obligate wildlife species that depend on sagebrush habitat for part or nearly all of their life-history needs. These sagebrush-obligate species include the pygmy rabbit (*Brachylagus idahoensis*), sagebrush lizard (*Sceloporus graciosus*), pronghorn (*Antilocapra americana*), sagebrush vole (*Lemmyscus curtatus*), Brewer’s sparrow (*Spizella breweri*), sage thrasher (*Oreoscoptes montanus*), sagebrush sparrow (*Artemisiospiza nevadensis*), greater sage-grouse (*Centrocercus urophasianus*), and Gunnison sage-grouse (*C. minimus*) (Rowland et al., 2006; Wisdom et al., 2011). Although many sagebrush landscapes are not considered particularly floristically diverse (West and Young, 2000), intact or lightly-impacted sagebrush landscapes in some regions can support relatively species-rich plant communities, with high levels of diversity found both within and among individual sites (e.g., Seipel, 2006; Shinneman et al., 2008). Forb species richness is generally higher, but typically with less cover and biomass, compared to grasses. Other species groups are not as well studied across the sagebrush biome; however, some sagebrush communities have been shown to support a rich diversity of insect, lichen, and fungal species (Welch and Criddle, 2003; Miller et al., 2011a,b; Pilliod and Rohde, 2016).

The greater sage-grouse—a charismatic species of the sagebrush biome

The greater sage-grouse is a sagebrush-obligate species considered at risk throughout its range (Fig. 2). This large grouse species is perhaps best known for its flamboyant mating displays on lek sites, on which the males “strut” to attract female grouse, fanning their tail feathers and puffing their chests to inflate two bulbous air sacs that produce popping and whistling noises. In general, sage-grouse select relatively large, undisturbed sagebrush landscapes with minimal human activity (Aldridge et al., 2008). Greater sage-grouse depend on sagebrush for food, cover, nesting and brood rearing (Beck et al., 2009; Connelly et al., 2000, 2011). Optimal shrub cover

Fig. 2 The estimated historical distribution of the greater sage-grouse (*Centrocercus urophasianus*) and Gunnison sage-grouse (*C. minimus*) before EuroAmerican settlement and the approximate range distribution of contemporary sage-grouse populations. The sagebrush biome has been altered by fire, invasive species, cropland conversion, and human development (e.g., energy extraction, roads, housing, and powerlines) causing substantial declines in sage-grouse populations. Photo: U.S. Fish and Wildlife Service.

for greater sage-grouse is ~15–25% for nesting and early-season brood-rearing habitat (Stiver et al., 2015), but sagebrush cover and other structural requisites vary with seasonal life requirements and among populations in different parts of the distribution.

The greater sage-grouse has experienced substantial population declines and contraction of its historical range, prompting several (unsuccessful) petitions to list the bird for legally protected status under the U.S. Endangered Species Act. Human activities, such as energy development, roads, shrub removal, and conversion of habitat to cropland have fragmented or destroyed habitat, and currently, loss from fire is a predominant threat, especially in the western half of the sage-grouse range (Brooks et al., 2015), where increasing wildfire activity over recent decades is linked to dramatic sage-grouse population declines (Coates et al., 2016). As a result, land management agencies have recently developed sagebrush ecosystem management goals that focus on conserving sage-grouse habitat, including minimizing effects of wildfire (Chambers et al., 2017; see below). Because the greater sage-grouse is a wide-ranging, often migratory species that uses different sagebrush habitats during different seasons, it has been considered a potential “umbrella” species, whereby conservation of its broad extent and diversity of habitats would likely benefit numerous other sagebrush-associated species (Rowland et al., 2006).

Ecological Processes

Long term fluctuations in climate have influenced the distribution of sagebrush communities in western North America over many thousands of years, as well as the relative abundance of associated grass, forb, shrub, and tree species (Nowak et al., 1994; Mensing et al., 2013). Extreme climate events (e.g., drought) and disturbances operating over much shorter time scales, including fire, disease, and herbivory pressure, also influence the relative abundance of sagebrush species. Fire is particularly relevant to contemporary management and conservation of sagebrush ecosystems. Before EuroAmerican settlement, fire was infrequent in most sagebrush ecosystems, varying with climatic influence on fuel availability, fuel moisture, and ignition rates. Large portions of the pre-settlement sagebrush biome were likely affected by infrequently occurring large fires, resulting in landscapes characterized by large patches of mature sagebrush and some large grass-dominated areas (i.e., recovering from fire), with a superimposed, fine-scale mosaic of community structural conditions created by more frequent but smaller disturbance events (Bukowski and Baker, 2013). Historically, the average time between fires (i.e., mean fire return interval) ranged from a few decades in more productive, mesic sagebrush ecosystems near forest and woodlands (Miller and Heyerdahl, 2008) to hundreds of years or more in fuel-limited, hotter and drier sagebrush ecosystems or where summer precipitation limited fire spread (Baker, 2013). Most sagebrush species reestablish slowly after fire, as they lack capacity for re-sprouting or long-distance seed dispersal, and sagebrush seed viability is generally of short duration (Young and Evans, 1989). As a result, several decades or more may be required for full recovery to mature sagebrush habitat after fire (Shinneman and McIlroy, 2016), and trends of increasing fire frequency threaten the persistence of many sagebrush ecosystems, as discussed below.

Threats and Anthropogenic Stressors of Sagebrush Ecosystems

Since EuroAmerican settlement began during the mid-1800s, sagebrush ecosystems have undergone rapid and often irreversible conversion to human-developed landscapes and nonnative ecosystems that threaten the long term persistence of these communities and the myriad species they support. Historically, sagebrush was not a valued rangeland plant species, and conversion using fire or chemical and mechanical treatments were commonly imposed to increase forage for domestic livestock and improve water yields (Welch and Criddle, 2003). Sagebrush ecosystems are considered one of the most imperiled major ecosystems in North America (Noss and Peters, 1995), due to historical widespread over-grazing by domestic livestock, clearing of sagebrush to enhance livestock forage, conversion to cropland, urban expansion, and extensive fragmentation caused by energy development, road networks, and fuel treatments (Table 2). It has been estimated that ~45% of the historical area of sagebrush steppe and sagebrush shrublands has been lost (Miller et al., 2011a,b), mostly due to agriculture, but also from ecosystem type conversion (described below). Sagebrush communities of the Great Plains have also experienced substantial loss, particularly from cropland conversion and energy development.

Altered wildfire regimes coupled with the spread of invasive plant species pose a major threat to many sagebrush habitats (Knick, 2011), especially in drier sagebrush ecosystems in the western portion of the biome (Brooks et al., 2015) that have inherently low resilience to disturbance (i.e., slow recovery) and low resistance to invasion (Chambers et al., 2014). Nonnative annual plants, especially cheatgrass (*Bromus tectorum*), readily invade many sagebrush landscapes, establish quickly in burned areas, outcompete native perennials, and form continuous fine fuels that are highly ignitable and facilitate wildfire spread. The resulting “invasive plant–fire regime cycle” (Fig. 3) is characterized by both greater fire frequency, which retards shrub and perennial grass recovery, and promotes expansion of fire-prone, nonnative plant communities (Brooks et al., 2004). During a recent 30-year period (1984–2013), about 8.4 million ha burned in Great Basin rangelands alone, including areas that burned multiple times, some with mean fire return intervals <7.5 years (Brooks et al., 2015). Cheatgrass already dominates vast acreages in the Great Basin (Bradley and Mustard, 2005; Boyte and Wylie, 2016), and evidence suggests this nonnative species is contributing to increasingly larger fires (Balch et al., 2013), some of which have exceeded 200,000 ha in size (Brooks et al., 2015). Recent wildfire activity suggest these trends are likely to continue (Fig. 4), and future climate change could bring even more wildfire, as discussed below.

Effects of Climate Change

Directional trends in climate over the past several decades are evident across the sagebrush biome and throughout much of the western United States, including increasing temperatures, a longer frost-free season, and a declining snowpack (Kunkel et al., 2013; Mote et al., 2018). However, broad-scale trends in precipitation are difficult to discern and generally more variable across the region. Estimates derived from global circulation models (GCMs) project continued warming for the region throughout the next century. However, projected temperature increases vary among GCMs and are further dependent on the radiative forcing (greenhouse gas concentration) trajectories being modeled, as depicted in the representative concentration pathways (RCPs) developed for the Intergovernmental Panel on Climate Change [IPCC] (2014) to reflect future potential warming scenarios. Chambers et al. (2017) summarized climate projections from an ensemble of 11 GCMs across the sagebrush biome through the end of the 21st century, and found that average temperatures are expected to increase over the recent past (1980–2010) by a range of 2–5 °C to 3–7 °C using RCP pathways representing eventual stabilization (RCP4.5) versus steadily increasing (RCP8.5) radiative forcing, respectively, while precipitation projections ranged from a slight decrease (~10% decline) to substantial increases (up to 50%) over the long-term, reflecting considerable variability among models concerning future precipitation trends. Although climate change and its effects are expected to vary spatially, even if portions of the sagebrush biome receive more precipitation on average, less of it is predicted to fall as snow (Klos et al., 2014) and higher evapotranspiration rates are expected due to longer and hotter growing seasons (Palmquist et al., 2016). Thus, seasonal interactions between shifts in temperature and precipitation may effectively increase aridity and reduce plant available soil water, resulting in possible elevational or latitudinal range shifts by big sagebrush (Schlaepfer et al., 2015), or possibly an overall loss in climatically suitable habitat (Still and Richardson, 2015). A recent multi-model analysis by Renwick et al. (2018) suggested big-sagebrush in cooler and more mesic location might actually benefit from climate change, while big sagebrush in warmer locations, that are generally less resistant to invasion and less resilient after disturbance, are likely to decline.

In addition to directly affecting the distribution and abundance of individual sagebrush species, climate change may also impact sagebrush ecosystem composition and function by further altering disturbance regimes. More fire activity is likely if climate change increases the duration of fire-prone weather or enhances growing conditions for fire-prone species (Abatzoglou and Kolden, 2011). Indeed, some models predict climate-enhanced wildfire activity in the future, including higher probabilities of large fires, across much of the arid and semiarid portions of the western U.S. (Barbero et al., 2015). Over the near-term, warmer temperatures combined with wetter early growing-seasons could promote the productivity of cheatgrass and other nonnative annuals (Boyte et al., 2016), affecting the distribution of fine fuels that increase the potential for large and frequent fires (Bradley et al., 2018). Under frequent-fire dynamics, carbon storage would likely be reduced across the sagebrush biome and could convert the region from a carbon sink (net storage) to a carbon source (net loss/emission) (Bradley et al., 2006). However, complex, long-term future interactions between climate, fire, and vegetation remain difficult to predict with great certainty, and some areas could eventually experience less fire over time if fuels become increasingly limited under increasingly arid conditions. Ongoing research and observations are needed to better address this uncertainty and to facilitate management adaptation to changing conditions.

Table 2 Anthropogenic stressors that threaten the health or persistence of sagebrush ecosystems, and associated management and conservation actions that may alleviate these ecologically negative consequences.

<i>Threat/stressor description</i>	<i>Primary causes/sources</i>	<i>Potential management and conservation actions</i>
Human development: Human development can reduce or degrade sagebrush habitat, and threaten the viability of sagebrush-dependent wildlife, such as sage-grouse. Development impacts may occur individually or collectively, and include direct habitat conversion or indirect impacts via habitat fragmentation or by facilitating spread of invasive species	• Energy/mineral extraction and exploration • Conversion to cropland • Urban and exurban expansion • Infrastructure (e.g., roads, powerlines) • Associated human activity (e.g., increases in vehicle traffic, human-caused fires, recreation)	• Manage activities to minimize fragmentation, maintain landscape-scale connectivity, and limit risk of unintentional ecological change (e.g., exotic species invasions) • Limit or prohibit damaging activities in most sensitive habitats • Restore habitat and connectivity from past activities where feasible • Utilize minimum impact resource extraction technologies and methods • Utilize public land management planning, conservation designations, and cooperative arrangements among land-owners across boundaries to protect habitat and landscape-scale ecological processes
Livestock grazing: Livestock grazing impacts vary widely over time and space (i.e. environmental settings) and can be relatively benign, but heavy grazing by domestic livestock (cattle, sheep), especially without adequate rest, can reduce native herbaceous composition, structure, and productivity; damage biological soil crust; and increase the probability of exotic, annual grass invasion, especially at mid- to low-elevations. Effects can also vary regionally, as prior to EuroAmerican settlement, large ungulate grazing was relatively uncommon in the western portion of the sagebrush biome. Grazing intensity can also interact with limited and variable precipitation in sagebrush ecosystems, resulting in slow or delayed recovery / regrowth of plants	• Domestic livestock grazing is ubiquitous across federal, state, and private lands in the sagebrush biome • Unregulated grazing that began in the mid- to late-1800s and continued until after passage of the U.S. Taylor Grazing Act in 1934 likely had substantial and persistent impacts on sagebrush communities, especially where it damaged biological soil crusts and facilitated the historical expansion of cheatgrass	• Utilize ecologically sustainable stocking levels, rest periods, and seasonal rotation across landscapes • Minimize or restrict grazing in the most ecologically sensitive habitats, and after fire to promote recovery • Manage grazing animals to promote healthier ecosystems or to minimize adverse ecological consequences, including using strategically placed and timed grazing to reduce fuel loads in exotic species-invaded, fire-prone environments • Manage timing and placement of livestock to support post-grazing recovery of important seasonal wildlife habitats
Nonnative plant species: Nonnative plant species have invaded vast areas throughout the sagebrush biome, threatening habitat for native species, decreasing forage quality, and altering important ecological processes, including nutrient cycling and fire regimes	• Spread and dominance of exotic annual grasses (e.g., cheatgrass) and forbs, especially in drier-warmer environments that are less resistant to invasion • Intentionally introduced nonnative perennial grasses meant to improve forage for livestock that persist as dominant communities and can displace native plant species	• Utilize resistance and resilience concepts to prioritize and design effective restoration treatments for areas most in need and most likely to have successful outcomes • Prioritize postfire seeding and planting treatments in areas with high potential for exotic species invasions • Minimize future invasions through enhanced wildfire suppression efforts and land use management practices (see below)

(Continued)

Table 2 Anthropogenic stressors that threaten the health or persistence of sagebrush ecosystems, and associated management and conservation actions that may alleviate these ecologically negative consequences.—cont'd

Threat/stressor description	Primary causes/sources	Potential management and conservation actions
Altered wildfire regimes: Fire regimes across much of the sagebrush biome are no longer within their historical ranges of variability, with larger fire sizes and higher fire frequency, creating conditions that can eventually prevent recovery of native sagebrush communities	• Fire-prone, nonnative annual grasses that provide continuous fine fuels that drive larger and more frequent fires (invasive plant–fire cycle, Fig. 3) • Increasing rates of human ignited fires, especially near roads and populated areas • Changing climate that enhances fire-weather conditions, fire-prone species dispersal, and fuel loadings	• Where feasible, prioritize wildfire suppression activities to protect remaining intact sagebrush communities and wildlife habitat • Utilize fuel reduction treatments (targeted grazing, planting fire-resistant plants, mechanical reduction of biomass) where ecologically beneficial (e.g., avoid disturbing intact sagebrush communities), including carefully planned and constructed fuel break networks • Restore fire-prone, annual-grass invaded sagebrush communities, using native species where feasible • Control invading trees caused by past land use with low-impact mechanical treatments (e.g., individual tree removal) that permit retention of sagebrush cover valuable to wildlife • Prioritize treatments in or near essential wildlife habitat or where tree invasion elevates risk of altering ecological processes (e.g., increasing fire severity) • Avoid treatments in persistent and old-growth woodlands (that also have high value to wildlife) or where woodland removal enhances risk of nonnative species invasions
Native woodland expansion: Woodland tree species, particularly piñon pines (<i>Pinus</i> spp.) and junipers (<i>Juniperus</i> spp.) have expanded into adjacent sagebrush communities in portions of the sagebrush biome or have become denser, particularly in higher elevation sagebrush communities. While woodlands are an important native habitat, this shift in native ecosystem boundaries can result in loss of habitat for sagebrush-dependent wildlife, altered fire regimes, changes in composition and cover of plants, and altered hydrologic processes	• Natural, climate-driven expansion of woodland-shrubland ecotone over time • Influence of land uses that favor tree establishment and dominance, including livestock grazing and fire exclusion • Recovery from historical clearing of woodlands during early EuroAmerican settlement • Changing climate and enhanced atmospheric CO₂ that enhance tree species establishment and growth	• Recognize potential changes to sagebrush, including identifying systems that may become less resistant to invasion or less resilient to disturbance with climate change • Prioritize conservation/protection of important habitats (e.g., where future restoration under climate change may be most challenging) • Recognize potential for shifts in wildlife habitat utilization based on shifts in plant community composition and structure • Use climate forecasts and expected shifts in vegetation-fuel conditions to plan for wildfire control • Carefully manage livestock grazing intensity to reflect changing sensitivity of ecological conditions under climate variability/change
Climate Change: Variations in climate over space and time, especially water availability, are important determinants of sagebrush species distributions and abundance. Timing of precipitation can affect the relative abundance of shrubs vs. grasses, as well as contribute to the spread and dominance of invasive plants. Warming temperatures and altered precipitation regimes create new variations in plant composition and can affect the abundance and condition (e.g., moisture) of fuels that drive wildfires. Droughts limit forage available for wildlife and livestock	• Anthropogenic climate change caused by enhanced atmospheric CO₂ and other green-house gas concentrations • Climate variability occurring over different time periods (seasonal, annual, decadal) • Climate-driven disturbance events (e.g., fire, drought) • Ecophysiological response of plants to climate variability and long-term climate shifts (e.g., sagebrush shrubs typically take advantage of deep soil-water provided by winter precipitation—changes in the timing and type of precipitation may change soil hydrology and sagebrush community patterns)	• Recognize potential changes to sagebrush, including identifying systems that may become less resistant to invasion or less resilient to disturbance with climate change • Prioritize conservation/protection of important habitats (e.g., where future restoration under climate change may be most challenging) • Recognize potential for shifts in wildlife habitat utilization based on shifts in plant community composition and structure • Use climate forecasts and expected shifts in vegetation-fuel conditions to plan for wildfire control • Carefully manage livestock grazing intensity to reflect changing sensitivity of ecological conditions under climate variability/change

Multiple stressors can interact to push sagebrush ecosystems past ecological thresholds, making natural recovery unlikely and restoration efforts difficult, expensive, and uncertain.

Fig. 3 Schematic illustration of the transition from a native sagebrush community (A–D) to an annual grassland (E–I) via the “invasive grass-fire regime cycle.” Historically, landscapes dominated by sagebrush ecosystems (A) often had relatively discontinuous fuel loadings, with sparse bunchgrasses and native forbs in the interspaces (B), that burned relatively infrequently (C), and required up to several decades or more to recover from loss of shrub cover (D) and eventually back to mature shrub conditions (B). Exotic, fire-prone, annual grasses (especially cheatgrass) and forbs have invaded much of the sagebrush biome, filling the interspaces and providing continuous fine fuel loadings (E) that dry early in the growing season and facilitate large fires (F). With mortality of native species after fire (G), these fire-adapted nonnative species rapidly germinate, dominate the seed-bank, and spread in the postfire environment (H), outcompeting slower-recovering native species. These highly-flammable annual grasslands are prone to frequent fires (I) that prevent native species reestablishment, especially shrubs, without intensive and expensive restoration efforts (many of which are either unsuccessful or only partially restore native ecosystem structure and function). The exotic annual grass community does not provide suitable habitat for sagebrush-obligate wildlife species, such as the greater sage-grouse. Direction and color (transitioning from *green* to *yellow* to *orange*) of the straight arrows represent the annual plant invasion process, with *white-dashed circles* showing the transition from native bunchgrasses to nonnative annual grasses (i.e., increasing cover of *Bromus tectorum*) in the shrub interspaces. The downward (*dark-orange*) arrow indicates facilitation of the invasion process via fire, representing complete ecosystem type conversion. The size of the fire cycle-succession circles roughly correspond to the proportional difference in the mean fire return interval between the historical fire regime (in *green*, decades to hundreds of years between fires) relative to the invasive grass fire regime cycle (in *dark-orange*, < 15 years between fires). The dashed-orange line represents the crossing of an ecological threshold, after which conversion back to a native community condition becomes prolonged, improbable, or even impossible. Photos: USGS, BLM.

Conservation Strategies

Conservation of sagebrush ecosystems is critical for the myriad species they support (Wisdom et al., 2005; Rottler et al., 2015). Various mechanisms for conservation of sagebrush ecosystems exist, ranging from implementing sagebrush-favorable land use policies and designations, protecting intact sagebrush habitat from wildfire, and restoring degraded and disturbed sagebrush habitat, especially after fire, to prevent the continued spread and dominance of cheatgrass and other nonnative species (Table 2). Although about two-thirds of sagebrush landscapes fall on federally-managed lands, most are managed for multiple uses that are not necessarily compatible with conservation goals (Knick, 2011). Moreover, < 3% of the land area of sagebrush ecosystems and < 1% of sage-grouse habitat fall within more strictly protected designations, such as national parks and federally designated wilderness areas, and even many of these protected areas permit livestock grazing or other activities (e.g., mining) that may be counterproductive to certain sagebrush habitat conservation objectives (Knick et al., 2003; Knick, 2011).

Protected areas also do not prevent the devastating effects of invasive-grass wildfire interactions that continue to threaten ecologically valuable sagebrush habitat for sagebrush obligate species such as sage-grouse. Between 2015 and 2017 alone, more than 1.3 million ha of sage-grouse habitat burned in the western U.S. (U.S. Department of the Interior, 2017). Restoration of burned sagebrush ecosystems is not easily achieved in harsh, arid climates and across remote landscapes, and post-fire rehabilitation and restoration outcomes do not always meet the habitat needs of sagebrush-dependent species (Arkle et al., 2014). Thus, one

Fig. 4 Recent (2000–18) wildfire activity in the central-western portion of the sagebrush biome shown in relation to sagebrush-dominated landscapes.

strategy being promoted and implemented by federal land managers in the Great Basin is the construction of tens of thousands of kilometers of “fuel-breaks” (i.e., strips of land regularly cleared or mowed to reduce fuel loads, or planted with fire-resistant nonnative species) that are intended to limit the spread of wildfire in sagebrush landscapes. Unfortunately, the benefits of fuel breaks are uncertain, in part because their potential negative effects on sagebrush-dependent wildlife, including fragmentation of habitat, are largely unknown (Shinneman et al., 2019).

Ultimately, there are no easy solutions to conserving remaining sagebrush habitat across the vast reaches of the sagebrush biome. However, obtaining a better understanding of land use and management effects on sagebrush communities, estimating potential future risks, and seeking greater cooperation among state, federal, and private land owners to protect the sagebrush biome will be critical. Scientific research can facilitate these objectives, by investigating and elucidating the complex and dynamic interactions occurring among climate, wildfire, invasive species, and land use within sagebrush communities. This enhanced scientific understanding will improve our capacity to prioritize sagebrush landscapes for restoration and conservation action, protect important wildlife habitat they provide, and anticipate management outcomes under future climate change.

Abstract

Pinyon and juniper woodland is a major biome type centered on the Basin and Range and Colorado Plateau physiographic regions of interior western North America. It covers over 40 million ha from western Oregon in the northwest United States, eastward to Wyoming and southward to northern Chihuahua in Mexico, then westward to Baja California. Climatically, these woodlands lie within both the warm and cold temperate zones of North America but at the wetter and cooler portion of the semiarid realm where precipitation seldom exceeds 400 mm. This biome occupies a unique environmental envelope within North America, and with it comes a diverse complement of plant and animal species with the center of their ranges within its confines, and a wide variety of vegetation communities. The communities are characterized by low-statured woodlands and forests dominated by pinyon (nut pines) in combination with juniper trees. At lower elevations junipers tend to prevail and typically form very open-canopied woodlands of scattered trees in a shrubland or grassland matrix (shrubby woodlands and grassy woodlands or savannas, respectively). With increasing elevation, pinyons become more prevalent and co-dominate with junipers to form moderate-canopied woodlands and closed-canopied forests. Fire is integral to the dynamics of these woodlands ranging from high-frequency, low-intensity surface fires in grassy woodlands to low-frequency, high severity canopy fires in the forest communities. Across their domain, pinyon–juniper woodlands have been economically important in the lives of the people of western North America for millennia, from the harvesting of pinyon nuts and hunting to fuel wood gathering and livestock grazing. But now, given a growing human population in the region, increased landscape fragmentation, and potential climate change impacts, particularly on water availability, this biome is on the cusp of a transformation not yet seen in its history.

Introduction

Pinyon and juniper woodland is a major biome type centered on the Basin and Range and Colorado Plateau physiographic regions of interior western North America (Fig. 1). It covers over 40 million ha from western Oregon in the northwest United States, eastward to Wyoming and southward to northern Chihuahua in Mexico, then westward to Baja California (Kyllo, 2016). These are

Fig. 1 Distribution of pinyon-Juniper woodlands in the United States. From Evans, R. (1988). *Management of pinyon-juniper woodlands*. General technical Report INT-249. Ogden, UT: Intermountain Research Station.

low-statured (<10 m) woodlands dominated by pinyon, or nut, pines in combination with juniper trees (Fig. 2). At the lower elevations of valley plains, plateaus, and foothills, junipers tend to prevail and typically form very open-canopied (>10%–25% canopy cover) stands consisting of scattered trees in a shrubland or grassland matrix (colloquially known as “juniper savannas,” although the use of “savanna” is a recent adoption of a term originally used to describe tropical and sub-tropical grassland plains with trees, which have different ecological context for their structure than those in N. America). With increasing elevation, pinyons become more prevalent and co-dominate with junipers to form moderate-canopied woodlands between 25% and 70% cover. Farther up mountain slopes, pinyons clearly dominate with junipers in the sub-canopy forming nearly closed-canopied forests that border on montane forests dominated by tall pines and firs.

Climatically, these woodlands lie within the wetter and cooler portion of the semiarid realm where precipitation seldom exceeds 400 mm. While summer precipitation becomes predominant in the eastern portion of the distribution, winter precipitation stored in the soil profile is crucial to sustaining these tree species throughout their ranges, particularly during summer drought years. Increasing temperatures at lower elevations leads to greater evaporative demand and limits the lower-elevation range of the type while extreme cold and competition from more mesic and productive species may limit the woodlands at upper elevation. Within this semiarid framework, fire plays a complex role in ecological dynamics from the tree to landscape level, varying in intensity and frequency with differences in composition and structure across the woodland domain. For example, following fires where shrubs were prevalent in the understory, successional communities dominated by shrubs such as mountain mahogany or oaks may prevail as long-standing elements of pinyon-juniper woodland landscape. Similarly, under natural conditions repeated fires in open-woodlands with a grassy matrix may prevent successful pine and juniper reproduction that would otherwise lead to expansion of the biome.

Overall, this biome occupies a unique environmental envelope within North America, and with it comes a diverse complement of plant and animal species with the center of their ranges within its confines. For example, 90% of the range of Pinyon Jays, a bird species dependent on nut-producing conifers, lies within the distribution of the four pinyon pine species. In turn, the birds are important dispersers of pinyon pine nuts leading to tree regeneration (Boone et al., 2018). Similarly, gray vireos are tied to the range of juniper species within the biome. The flora is diverse, with its share of endemics (43 species; Siviniski and Knight (1996) and Goodrich et al. (1997)) as well as a wide range of vegetation communities across the biome (150 plant associations; see Pinyon-Juniper Types section below).

Across their domain, pinyon-juniper woodlands have been economically important in the lives of the people of western North America. Pinyon nuts were not only nutritionally valuable, they have played a central cultural role among indigenous peoples and later in colonial Euro-American communities. Similarly, while the woodlands provide limited timber resources, they have provided fuel wood to all communities over the centuries into the present day. Beyond this, livestock grazing has been a nearly constant element of the landscape since European settlement and has a significant influence on land management practices. But now, given a growing human population in the region, increased landscape fragmentation, and potential climate change impacts, particularly on water availability, this biome is on the cusp of a transformation not yet seen in its history.

Fig. 2 Pinyon-juniper woodlands have a broad range of structure and composition across the biome including: (A) open grassy savanna-like woodlands with short trees in a grassy matrix; (B) open shrubby woodlands (or wooded shrublands) with shrubby inter-tree spaces; (C) closed-canopy long-lived, persistent forests with relatively tall trees with a mix of shrubs, grasses, and forbs in the understory; and (D) very open, often sparse woodlands on cliffs, escarpments and other rocklands. Photos: A, C, and D by E. H. Muldavin; B by F. A. Martin.

Types of Pinyon–Juniper Woodlands

Given its wide distribution and environmental complexity, the pinyon–juniper (P-J) woodland biome offers a wide diversity of vegetation types (some 150 plant associations have been identified across the P-J domain). Using the International Vegetation Classification (IVC) framework (Faber-Langendoen et al., 2014, 2017), P-J woodlands occur in both warm-temperate and cool-temperate forest and woodland formations that reflect climates with relatively warm winters versus cold winters, respectively (Table 1). Within the warm-temperate formation, the woodlands are further subdivided geographically into California and Madrean-Balconian divisions corresponding to west coast versus southwestern United States and Mexican distributions, respectively. The California P-J woodlands are dominated by California juniper (*Juniperus californica*) and four-needled or Parry's pinyon (*Pinus quadrifolia*) whose distribution is strongly influenced by the Mediterranean-like winter precipitation-dominated climate of southern California, southwestern Arizona, and adjacent Baja California in Mexico. In contrast, in Madrean-Balconian woodlands, monsoonal summer precipitation is predominant and P-J woodlands fall within Madrean Lowland Evergreen Woodlands dominated by a different set of pinyons—border pinyon (*P. cembroides* and *P. discolor*) and to a limited degree two-needled pinyon (*P. edulis*)—along with junipers such as redberry juniper (*Juniperus coahuilensis*), alligator juniper (*J. deppeana*), dropping juniper (*J. flaccida*), and Pinchot's juniper (*J. pinchotii*).

The cool-temperate P-J woodlands are represented by the Western North American Pinyon–Juniper Woodland and Scrub Division and are further divided into Intermountain Pinyon–Juniper versus Southern Rocky Mountain Two-needle Pinyon–Juniper Woodland macrogroups. The former includes woodlands of Great Basin, Colorado Plateau, and Colorado Plateau regions where winter precipitation is dominant and the winters can be very cold; summer precipitation is dependent on the extension of the “Arizona” monsoon from the south, which can be erratic. These woodlands are dominated by either singleleaf pinyon (*P. monophylla*) to the west or two-needle pinyon to the east in combination with Utah juniper (*Juniperus osteosperma*). Western juniper (*J. occidentalis*) occurs in the far northwest of the domain usually without pinyons. Included here are also curl-leaf mountain-mahogany (*Cercocarpus ledifolius*) shrubby woodlands which can be prevalent across the Great Basin. At lower elevations, these P-J woodlands can border on cold-desert shrublands and grassland communities while at upper elevations they grade to pine and mixed-conifer forests.

Table 1 A classification of pinyon-juniper woodlands following the International Vegetation Classification hierarchy (see Faber-Langendoen et al., 2014, 2017 for definitions of the hierarchy elements). For each level there is a database code per the US National Vegetation followed by the type name (complete descriptions of each element are available at the US National Vegetation Classification website: <http://usnvc.org/>).

		A3577	Southern Rockies Pinyon–Juniper Grassy Woodland Alliance
		A3576	Two-needle Pinyon–One-seed Juniper Shrubby Woodland Alliance

To the southeast, the Southern Rocky Mountain Two-needle Pinyon–Juniper Woodland macrogroup prevails along the flanks of the southern Rocky Mountains and among the mountains, plains, and mesa tablelands of Arizona and New Mexico. In this summer-precipitation-dominated climate, singleleaf pinyon and Utah juniper drop out and two-leaf pinyon and one-seed juniper (*J. monosperma*) dominate the woodlands (singleleaf pinyon at higher elevations and one-seed juniper at lower). At lower elevations to the east these woodlands border on grasslands of the southern Great Plains, and to the south they can intermix with Chihuahuan Desert grasslands and scrub.

Detailed Pinyon–Juniper Woodland Descriptions

The following are summary descriptions of pinyon–juniper woodlands at the group level of the IVC (detailed descriptions of each group and its constituent alliances can be found at the US National Classification webpage (USNVC.org). Descriptions are ordered by the hierarchically in Table 1.

G198 Californian Conifer Forest & Woodland Group

Californian Conifer Forest & Woodland Group includes a variety of cypress and pine forests and woodlands along with pinyon–juniper woodlands of the Transmontane Desert Pinyon–Juniper Woodland Alliance.

Environment: These woodlands are found in the montane regions of southern California extending to the western edge of the Mojave Desert and southward into northern Baja California, Mexico. Stands occur on ridges, slopes, valleys, alluvial fans, valley bottoms at elevations ranging from 600 to 2450 m. Soils are porous, rocky, coarse, sandy or silty, and often very shallow.

Vegetation structure and composition: This alliance consists of scrub woodlands, generally < 5 m in height, where *Juniperus californica* is codominant with Parry pinyon or singleleaf pinyon. In some stands, the junipers are open-grown trees over grassy understories. In others, the junipers form mixed stands with pinyon. The understory often has Mojave Desert shrubs such as blackbrush (*Coleogyne ramosissima*), Mormon tea (*Ephedra* spp.), and scrub oaks such as Muller oak (*Quercus cornelius-mulleri*).

G487 Madrean Juniper Open Woodland Group

Environment: This Madrean juniper woodland and savanna occurs at lower-elevations within the range of the macrogroup from northern Mexico into the southwestern United States. Savanna-like stands occur primarily on loamy rolling plains, alluvial fan piedmonts, plateaus, and lower foothill slopes while the more closed-canopied woodlands are found on cooler aspects of steeper slopes with generally shallow rocky soils.

Vegetation structure and composition: These savannas and woodlands have open to moderately closed tree canopies (10%–60% cover). The lack of pinyon trees and the dominance of the Madrean junipers redberry juniper or alligator juniper are diagnostic. At the northern end of the range, one-seed juniper may replace redberry. Madrean oak trees may be present but do not dominate the tree canopy.

The woodland understories are usually dominated by species with Sierra Madrean affinities. Some communities are distinctly shrubby and make up the Madrean Juniper /Shrub Open Woodland Alliance of associations that may include chaparral species (e.g., manzanita, ceanothus, mountain mahogany, yuccas, and scrub oaks) or warm desert scrub elements (e.g., creosote bush, lechuguilla and mesquite). In contrast, the associations of Madrean Juniper/Grass Open Woodland Alliance have often luxuriant grassy understories and a high mix of forbs and few shrubs. Common Madrean grasses include bull muhly, curlyleaf muhly (*M. setifolia*), and Texas bluestem (*Schizachyrium cirratum*), but elements from more northern woodlands and plains may be prevalent such as blue grama (*B. gracilis*), hairy grama (*B. hirsuta*), or sideoats grama (*B. curtispendula*).

G200 Madrean Pinyon–Juniper Woodland Group

Environment: This P-J woodland group is common in higher foothills, mountains and plateaus within the range of the southwestern United States and northern Mexico. Sites range from gentle to steep slopes. Ground cover often has high cover of rock or bare ground. Elevations range from 1700 to 2200 m. Substrates are variable, but soils are generally shallow, dry and rocky often with rock outcrops.

Vegetation structure and composition: These vegetation communities are characterized by open to moderately closed tree canopies (10%–60% cover and occasionally greater) dominated by Mexican pinyon (*Pinus cembroides* and its variations) and juniper trees that can range from 2 to 10 m in height. Alligator juniper (*Juniperus deppeana*), drooping juniper (*J. flaccida*), or redberry juniper (*J. coahuilensis*) may be common or co-dominant. Two-leaf pinyon and one-seed juniper may become the dominants in the northern distribution of the group. Madrean oak trees may be present but do not dominate the tree canopy.

The understories are usually dominated by species with Sierra Madrean affinities. Some communities are distinctly shrubby and may include chaparral species such as manzanita (*Arctostaphylos* spp.), desert ceanothus (*Ceanothus greggii*), mountain mahogany (*Cercocarpus montanus*), yuccas, and scrub oaks and belong to the Madrean Pinyon–Juniper /Shrub Woodland Alliance. In contrast, the Madrean Pinyon–Juniper/Grass Woodland Alliance has associations that often have luxuriant grassy understories and a high diversity of forbs and few shrubs. Common Madrean grasses include bull muhly (*Muhlenbergia emersleyi*), New Mexico muhly (*M. pauciflora*), and pinyon ricegrass (*Piptochaetium fimbriatum*).

G900 Colorado Plateau Pinyon–Juniper Woodland Group

Environment: This P-J woodland group occurs in dry mountains and foothills of the Colorado Plateau region including the western slope of Colorado and the Wasatch Range, south to the Mogollon Rim, and east into the northwestern corner of New Mexico. Winter precipitation in the form of snow predominates while summers can be warm to hot. Elevations range from 1500 to 2440 m. Sites often have high cover of rock or bare ground and soils are generally shallow, dry and rocky often with rock outcrops.

Vegetation structure and composition: These communities are characterized by stands with moderate to closed tree canopies (30%–60% cover and occasionally greater) which are dominated by twinleaf pinyon and Utah juniper trees that can range from 2 to 10 m in height.

A suite of communities are distinctly shrubby and make up the Foothill & Lower Montane Pinyon–Juniper/Shrub Dry-Mesic Woodland, Colorado Plateau Utah Juniper Shrubby Woodland, and Colorado Plateau Two-needle Pinyon–Utah Juniper Open Woodland alliances representing over 40 plant associations. These associations may include montane chaparral species such as manzanita (*Arctostaphylos* spp.), desert ceanothus (*Ceanothus greggii*), mountain mahogany (*Cercocarpus montanus*), yuccas, and scrub oaks, or cold desert shrubs such as sagebrush (e.g., *Artemisia tridentata*, *A. nova*) and antelope bitterbrush (*Purshia tridentata*).

In contrast, Two-needle Pinyon–Utah Juniper Grassy Open Woodland and Utah Juniper Grassy Open Woodland alliances are made up of associations with grassy understories that are commonly dominated by cool-season (C3) grasses. These thrive on winter moisture and the cooler temperatures of early summer, e.g., needle and thread grasses (*Hesperostipa comata*; *H. neomexicana*), bluebunch wheatgrass (*Pseudoroegneria spicata*) and Indian ricegrass (*Achnatherum hymenoides*). Cheat grass (*Bromus tectorum*) is also a cool-season grass that is nonnative and invasive that has become important in these communities, altering fire regimes and competitive relationships among the native grasses.

G248 Columbia Plateau Western Juniper Open Woodland Group

Environment: This P-J woodland group is found on the Columbia Plateau and extends to the northern and western margins of the Great Basin, from southwestern Idaho along the eastern foothills of the Cascades south to the Modoc Plateau of northeastern California. Elevations range from 200 to 1500 m. Soils are generally medium-textured, with abundant coarse fragments, and derived from volcanic parent materials.

Vegetation structure and composition: Western juniper is typically the only tree species and pinyons are absent. The tree form of curl-leaf mountain mahogany (*Cercocarpus ledifolius*) may also occasionally co-dominate. In Western Juniper Shrubby Woodland Alliance associations, the spaces between trees are dominated by tall shrubs such as big sagebrush or curl-leaf mountain mahogany along with rabbitbrush (*Chrysothamnus viscidiflorus*, *Ericameria nauseosa*) and antelope bitterbrush with a scattering of cool-season grasses. In contrast, the Western Juniper Grassy Open Woodland Alliance communities are dominated by cool-season grasses such as Idaho fescue (*Festuca idahoensis*), bluebunch wheatgrasses, and Sandberg bluegrass (*Poa secunda*) in the inter tree spaces and occasionally co-dominate with shrubs.

G899 Great Basin Pinyon–Juniper Woodland Group

Environment: This P-J woodland group occurs on dry mountain ranges of the Great Basin region and eastern foothills of the Sierra Nevada, and south in scattered locations throughout southern California. They are typically found at elevations from 1500 to 2600 m. Stands occur on warm, dry sites on mountain slopes, mesas, plateaus and ridges.

Vegetation structure and composition: The vegetation is characterized by stands with open to moderately dense tree canopy typically composed of a mix of singleleaf pinyon and Utah juniper. In some regions of southern California, Utah juniper is replaced by California juniper. There are two alliances where shrubs dominate the inter-tree spaces with or without a grass layer: Great Basin Singleleaf Pinyon–Utah Juniper Shrubby Woodland and Great Basin Utah Juniper Shrubby Woodland that lacks the singleleaf pinyon. The most common shrub dominants are big sagebrush, black sagebrush, little sagebrush (*Artemisia arbuscula*), curl-leaf mountain mahogany, littleleaf mountain mahogany (*Cercocarpus intricatus*), blackbrush (*Coleogyne ramosissima*), and antelope bitterbrush among others that are also elements of cold-desert communities found at lower elevations. Those associations that lack a strong shrub component belong to the Great Basin Singleleaf Pinyon–Utah Juniper Grassy Open Woodland where cool-season grasses such as basin wild rye (*Leymus cinereus*), needle and thread grass, and bluebunch wheatgrass tend to dominate between the trees.

G249 Intermountain Basins Curl-leaf Mountain-mahogany Woodland & Scrub

Environment: Stands of this woodland and shrubland group occur in hills and mountain ranges of the Intermountain West basins from the eastern foothills of the Sierra Nevada northeast to the foothills of the Bighorn Mountains of Wyoming. It typically occurs from 600 m to over 2650 m in elevation on rocky outcrops or escarpments and forms small- to large-patch stands in forested areas. Most stands occur as shrublands on ridges and steep rimrock slopes, but they may be composed of small trees in steppe areas.

Vegetation structure and composition: This woodland and shrubland group includes stands dominated by either the tree or shrub form of curl-leaf mountain mahogany. Scattered junipers or pines may also occur. Curl-leaf Mountain-mahogany Shrubby Woodland and Curl-leaf Mountain-mahogany Scrub alliances are typically co-dominant with other Great Basin cold-desert shrubs such as big sagebrush, antelope bitterbrush or more montane elements such as Gambel oak (*Quercus gambelii*), snowberry (e.g., *Symphoricarpos oreophilus*), or rockspirea (*Holodiscus dumosus*). The Curl-leaf Mountain-mahogany Grassy Woodland associations tend to have a high cover of cool-season grasses such as basin wild rye, Idaho fescue, and bluebunch wheatgrasses under the curl-leaf mountain mahogany.

G252 Southern Rocky Mountain Juniper Open Woodland Group

Environment: This P-J woodland and woodland-savanna group occurs along the eastern and southern foothill slopes of the southern Rocky Mountains and mesa tablelands, and plains of the southeastern Great Plains. They occur on a range of sites from steep, colluvial slopes of escarpments with rocky soils to lower toeslopes and valley bottoms and plains with loamy soils.

Vegetation structure and composition: Stands of this group typically have open tree canopies (10%–60% cover) that are dominated by short-statured (2–5 m) one-seed juniper (*Juniperus monosperma*). Two-needle pinyon may be present but usually growing within the canopy of the juniper. On plains, tablelands, and gentle foothill slopes, savanna-like stands develop with widely spaced juniper trees with lush perennial grass cover between trees (One-seed Juniper Grassy Woodland Alliance). Grasses tend to be warm-season

species that are prevalent in the adjacent plains and desert regions such as blue grama, sideoats grama, or galleta (*Pleuraphis jamesii*), but occasionally cool-season grasses such as needle and thread grass can dominate the sites. On the rockier, steeper sites, stands tend to have a strong shrub component, particularly scrub oak (e.g., *Quercus x pauciloba*) or mountain mahogany and belong to the One-seed Juniper Shrubby Woodland Alliance. In addition, yuccas and prickly pear or cholla cacti (e.g., *Opuntia phaeacantha* and *Opuntia imbricata*) can be common.

G253 Southern Rocky Mountain Pinyon–Juniper Woodland Group

Environment: This P-J woodland group occurs on dry mountains and foothills in southern Rocky Mountain in Colorado east of the Continental Divide down through the mountains and plateaus of northern New Mexico extending east into the southeastern Great Plains (on limestone and shale breaks, escarpments and hills). Stands are found on warm, dry sites on mountain slopes, mesas, plateaus, and ridges. Elevations range from near 1500 to 2900 m with high-elevation stands restricted to relatively warm, dry ridges and south and west aspects. Lower-elevation stands are often restricted to cooler north- and east-facing slopes. Soils vary in texture ranging from stony, cobbly, gravelly or sandy loams to clay loam or clay.

Vegetation structure and composition: The vegetation is characterized by two-needle pinyon that dominates or codominates the tree canopy with one-seed juniper. Rocky Mountain juniper (*Juniperus scopulorum*) may codominate or replace *Juniperus monosperma* at higher elevations. At higher elevations on mountain slopes stands can have the stature (> 10 m tall) and canopy closure (> 60% canopy cover) of forests. In contrast, at lower elevations tree size diminishes to as low as three meters and canopies become very open, forming woodland savannas. The forest-like woodlands have a mixture of grasses and shrubs in the understory and overall cover can be sparse. Most these communities belong to the Two-needle Pinyon–One-seed Juniper Shrubby Woodland Alliance where Gambel oak, mountain mahogany, and cool-season grasses such as Scribner needle and thread grass (*Achnatherum scribneri*) are prevalent. In contrast, the P-J woodland savannas of this group have a predominantly grassy inter-tree space and belong to the Southern Rockies Pinyon–Juniper Grassy Woodland Alliance. Grasses tend to be warm-season species that are prevalent in the adjacent plains and desert regions such as blue grama, sideoats grama, or galleta, but occasionally cool-season grasses such as New Mexico needle and thread grass can dominate the sites.

Ecological Dynamics in Pinyon–Juniper Woodlands

Fire Regimes

Fire is integral and a natural element in most pinyon–juniper woodlands, but the regimes vary depending on the environmental context and vegetation composition and structure. Among the types described above, three basic structural types emerge primarily at the alliance level: those woodlands with open canopies and grassy interspaces, those with moderate canopies and well-developed shrub strata, and those with near-closed, forest-like canopies with understories that are a mix of shrubs and grasses at low to moderate cover. These correspond roughly to three P-J fire regimes types described by [Romme et al. \(2009\)](#) as grass-dominated savanna, shrubby woodland (or wooded shrubland), and persistent woodland (the last also includes the woodlands of rocklands with little or no understory). These structural types are primarily driven by the amount of precipitation and its seasonality whereby winter precipitation that results in deep soil moisture storage will tend to favor trees and other deep rooted woody species while transient shallow summer moisture tends to favor more shallow-rooted grasses and forbs ([Fig. 3](#)). Accordingly, they have different proportions of tree, shrub, and grass fuels that generate different types of fire of frequencies and intensities. In general, under normal conditions savanna woodlands are likely to have low intensity fires that kill only small seedlings and sapling trees, keeping the stands open, but the fires can be spatially extensive since the stands commonly occur in gentle terrains of rolling hills and plains (fire regime type I). They also tend to happen more frequently than other P-J types because of the rapid recovery of grasses to a fire-ready state—every 10–30 years depending on the plant association ([Wright et al., 1979](#); [West and Young, 2000](#)).

Woodlands with significant shrub cover typically have mixed to high-severity regimes with some tree torching and top-killing of shrubs ([Fig. 4](#)). This is followed by a longer recovery period leading to somewhat lower frequencies, (perhaps 25–80 years; [Gori and Bate, 2007](#)). Spatially, under extreme conditions they can reach landscape scale, but more commonly they are small to large patch fires. Persistent woodlands with near-closed canopies tend to have moderate surface to high-intensity canopy fires that occur at frequencies from 60 to > 100 years or more, usually as small to medium patches, but extreme events can reach landscape scale ([Fig. 5](#)). There are also persistent woodlands of escarpment rocklands where fire is very rare or absent because of the spacing of trees and the lack of surface fuels.

Fire in P-J woodlands has been impacted by human activities, and particularly following European settlement beginning in the early 17th century ([Jacobs, 2008](#)). Historical fire regimes were disrupted following the introduction of livestock. Grazing passively suppresses fire by removing fine fuels needed to carry surface and low to mixed-severity fires that likely maintained the structure and composition of pinyon–juniper savannas and pinyon–juniper shrub woodlands historically. Active fire suppression was also practiced by the Federal government during the last 100 years ([Swetnam and Baisan, 1996](#)). As fire became less frequent, pinyon and juniper trees became denser and subsequent fires became more severe. Over the last century, a reduction in fire frequency has caused a conversion of some juniper savanna to juniper woodland, as well as invasion of juniper trees from areas of naturally low fire frequency, (e.g., rocky ridges) into adjacent communities, especially sagebrush steppe ([Wright et al., 1979](#); [West and Young, 2000](#); [Romme et al., 2009](#)). In contrast, nonnative grasses such as annual cheatgrass can quickly invade and promote increased fire frequencies, particularly in the western regions dominated by winter precipitation.

Fig. 3 A general framework for the distribution of three broad types of western pinyon-juniper woodlands with respect to soil moisture gradients and associated fire regimes. Fire regime classes adapted from Schmidt, K. M., Menakis J. P., Hardy C. C., Hann W. J. and Bunnell D. L. (2002). Development of coarse scale spatial data for wildland fire and fuelmanagement. *General Technical Report RMRS-87*. Fort Collins, CO: USDA Forest Service, Rocky Mountain Research Station.

Fig. 4 A firefighter crew hiking out from a wildland fire burning in a pinyon-juniper woodland along the Utah-Nevada border. Photo: Dan Jimenez, U.S. Forest Service.

Given a site's land use history and woodland type, post-fire responses can vary. Woodland savannas are likely to recover quickly if grass cover was not reduced by increased density of trees from fire suppression. That is, with increased density and more extreme fire events, burned sites will require a longer period for grasses to colonize bare zones left by dead trees and return the site to an optimal grassy fire-ready state. In shrubby woodlands where large patch or landscape-scale canopy fires have occurred, shrubs, particularly those that resprout after fire, can come to dominate the landscape and slow the tree recolonization process because

Fig. 5 Fire-patches in the Oscura Mountains of southern New Mexico based on comparative aerial photo analysis. Adapted from Muldavin, E., Baisan, C., Swetnam, T. DeLay, L. and Morino, K. (2003). *Woodland fire history studies in the Oscura and Northern San Andres Mountains, White Sands Missile Range, New Mexico*. Natural Heritage New Mexico Publ. No. 03-GTR-256. Albuquerque, NM: Natural Heritage New Mexico, University of New Mexico.

of seed source loss and competitive exclusion of those tree seedlings that do germinate. Response to extreme fire events in persistent woods may be similar, but localized seed sources may be more common and therefore likely provide more sites for successful seedling establishment to speed recovery to mature woodland.

Insect Pathogens

Although pinyon pines and junipers are drought tolerant, prolonged droughts can weaken trees and promote mortality by secondary agents. For example, trees play host to a set of endemic insect pathogens such pinyon bark beetle (*Ips confusus*) or cypress bark beetle (*Phloeosinus cristatus*), and associated fungal agents such as blackstain root-rot (*Leptographium wageneri*) that can cause whole stand die-offs that are often correlated with droughts (Clifford et al., 2008) (Fig. 6). These mortality events may be localized or widespread but can result in 50%–90% mortality of pinyon in affected areas (Harrington and Cobb 1988). Yet die-offs can be patchy even in local landscapes and there is more to be learned about the underlying mechanism of spread and specific triggers of outbreaks (Meddens et al., 2015).

Ecosystem Services and the Changing Land Use of Pinyon–Juniper Woodlands

The diversity of land use and ecosystem services in pinyon–juniper is as varied as the ecology, composition, and structure of these woodlands (Comer et al., 2003; Moir and Carlton, 1986; Romme et al., 2009). While we acknowledge the wide range of services that have supported subsistence and livelihood, including watershed function, plant production, and drinking water, we focus on some of the most important socioeconomics of woodlands and their land use legacies involving pine nut gathering, livestock use, and fuelwood. This narrow set of uses are broadly applicable to North American woodlands and are in large part the same uses that have affected their environmental conditions and trends, sometimes in positive feedbacks. Carbon storage is another key ecosystem service of pinyon–juniper that we consider in a later section on climate.

History and Land Use Impacts (e.g., Involving Herbivory, Changes in Fire Regime)

Pinyon nuts

In North America humans have a long history of exploiting pinyon–juniper woodlands for raw materials for building, medicine, and food that continues to this day (Cartledge and Propper, 1993; Mayes et al., 1989; Scurlock, 1998). Pinyon nuts are usually collected in early autumn directly from the tree by dislodging cones or seeds or by picking seeds from mature cones that have fallen to the ground (Gillihan, 2006). The brown nut shells within cones must be opened to expose the small nut inside. Immature cones can be opened by heating and the seeds roasted. The nuts are also eaten raw or boiled and were historically ground into paste or cooked in soups (Janetski, 1999). Roasted nuts lend themselves to long-term storage and were a key source of protein and fats to native people going back at least a couple of millennia (Bettinger, 1976; Lanner, 1981).

There is some evidence that the amount of pinyon nuts as a staple, and pinyon–juniper resources in general, fluctuated considerably in the southwestern United States. For instance by the 13th century AD, after hundreds of years of occupation, Puebloans had abandoned the Four Corners region perhaps as a result of deforestation of pinyon–juniper woodlands (Lekson and Cameron, 1995; Flint-Lacey, 2003). Archeological evidence indicates a time of widespread clearing of woodlands near the end of this period of Four Corners occupation (Litzinger, 2003). To the southeast, at present-day Bandelier National Monument in New Mexico, available evidence reveals significant changes to pinyon–juniper leading up to peak occupation of the area at about 1500 AD (Gottfried et al., 1995). Still, pinyon nuts remained important to native peoples of the Four Corners region for nutrition, medicine, and for ceremonial purposes (Mayes et al., 1989).

Today, nut gathering represents a pastime for some and an important cash crop for others, adding to the need for the sustainable management of woodland resources (Gottfried and Severson, 1994). Pound-for-pound pinyon nuts are by far the most value product of pinyon–juniper woodlands. By one estimate, the crop production in the species of two-needle pinyon alone is over 900,000 kg, though in some years commercial crops are nearly nonexistent (Ronco Jr, 1990). Commercial-scale crops occur on cycles of three to five years. Resource management that integrates permitting ensures that users can harvest what they need while preventing nuts from being over-collected and impacting the pinyon's ability to furnish other services such as tree regeneration and food for wildlife forage (Vander Wall and Balda, 1977; Stone, 1993).

Livestock use

The most widespread use of pinyon–juniper woodlands has been livestock grazing, especially for cattle and sheep (Aro, 1971; Gottfried et al., 1995). In many areas these woodlands offer essential spring and fall range resources for grazing animals. Though

consensus is lacking, there may also be some noneconomic advantages to light to moderate grazing of woodland understories including nutrient cycling, simulated gap disturbance, and stimulation of plant production (Milchunas, 2006). Economic and subsistence benefits to rural communities are clearly linked to the availability and quality of forage available to livestock in woodlands and other vegetation types, an ecosystem service dependency going back centuries (Allred, 1996; Scurlock, 1998).

Livestock grazing and fire suppression are the two most regarded agents of 20th-century change in pinyon–juniper, including increased tree densities through ingrowth along with the expansion of woodland into neighboring grasslands (Ronco Jr, 1990). Fire suppression coupled with land use patterns that are ubiquitous to fire-adapted woodlands of Mexico and the western United States have substantially reduced the frequency of fire. Past decades of overgrazing by livestock, and now management for uncharacteristically high levels of wild ungulates, has reduced grass competition to favor woody ingrowth of trees and shrubs. As a result, overutilization by both native and nonnative herbivores is often a component within a feedback system involving fewer fine fuels to facilitate fire spread that, in turn, promotes higher tree densities and decreased grass growth and forage availability (Allen, 2007; Gori and Bate, 2007). A notable effect of these agents in combination has been a major increase in juniper savannah cover types as grasslands submit to tree growth and woodland succession, expanding the pattern of reduced livestock forage. Increasing tree density in juniper savannah, and in fire-adapted pinyon–juniper generally, promote a positive feedback with elevated tree seed sources. While changes to woodland structure and composition have been linked to climate, there is some evidence to suggest that climate forcing is secondary to grazing and that the effects of grazing can be exacerbated by climate (Fuhlendorf and Smeins, 1997).

Resource managers and land owners have sought ways to reduce tree cover in pinyon–juniper, including woodland types where fire was infrequent and tree densities were characteristically elevated. In recent decades the drive for additional big game habitat has furthered efforts for woodland-to-grassland conversion. Among the approaches used to clear trees, the process of “chaining” began in earnest in the 1950s as a means to convert woodlands to enhance forage production. Though approaches vary, chaining often involves two bulldozers pulling a large chain, such as from a ship anchor, between them to knock down and uproot trees (Fig. 7). In recent years chaining has become more targeted and fallen out of use because of issues with soil erosion and habitat loss among other concerns (O’Meara et al., 1981).

While some woodlands have been converted to grassland, on balance the extent and density of pinyon–juniper has increased considerably, with pollen evidence suggesting that these woodlands are more abundant now than at any time in the past 5000 years (Miller and Wigand, 1994). The most remarkable changes in the structure of woodlands are concentrated in fire-adapted types that were historically more open and less connected. The over 40 million hectares occupied by pinyon–juniper in the intermountain United States represents an important resource for livestock management to be managed sustainably (Miller and Wigand, 1994).

Fuelwood

In Mexico and the western United States, pinyon–juniper woodlands have long been a major source of fuel for heating, cooking, and other uses. In the southwestern United States and Mexico the wood is still the main fuel in many rural communities. Pinyon–juniper woodlands have been used as a fuelwood source longer than any other of its provisioning services (Barger and Ffolliott, 1972; Ffolliott et al., 1999) and these tree species have exceptional heat content. On a given hectare there are about 58 cubic meters of wood volume (6.5 cords per acre). In the state of Nevada alone there are an estimated 125 million cubic meters of wood volume in pinyon–juniper woodlands (Born et al., 1992).

Fig. 7 Chaining of pinyon-juniper trees in southern Colorado, circa 1958. Note the chain is attached to a bulldozer on the left and one out of sight on the right. Photo by Jack Rottier, USDI Bureau of Land Management.

Beginning in the 19th century, these woodlands became a source of materials for many products including railroad ties, and a source of materials for mining operations, especially as fuel for processing metals but also for building materials for adits, shafts, and operations and processing facilities (Ffolliott et al., 1999). It follows that notable episodes of unsustainable use were concentrated near geologic resources and near human communities, as was likely the case with the decline of woodlands in the Four Corners region near the middle of the last millennium (Lekson and Cameron, 1995; Flint-Lacey, 2003). In the Chaco Canyon area of New Mexico, Samuels and Betancourt (1982) determined that human demography and fuelwood use of the time infers that woodlands would have been driven to depletion in about 200 years.

By the mid-20th century the demand for pinyon–juniper trees as a domestic fuel source gave the woodlands commercial value that peaked in the early 1980s (Born et al., 1992). Harvesting is done by commercial operators and by individuals for personal use, with private use representing the majority of cutting permits sold for federal lands (Wagstaff, 1987). Commercial woodyards exist in many urban centers of the western United States and on many tribal reservations, making the sale of fuelwood important for income and economies. In recent decades public land agencies have been driven to implement sustainable harvest policies with permitting and designated harvest areas. Such policies prevent local depletion of woodland resources despite that, in general, there has been a pronounced increase in the density and extent of pinyon–juniper woodlands (Gedney et al., 1999; Miller and Tausch, 2000). These woodlands collectively represent a vast resource capable of sustaining the production of fuelwood as a byproduct of the restoration and maintenance of ecosystem function.

Pinyon–Juniper Woodlands and Climate

A changing climate is altering the types and amounts of ecosystem services from pinyon–juniper. The vulnerability of these woodlands and the biodiversity and human communities that depend on them is based on their exposure to changing climate at a given location, their sensitivity to change, and their ability to adapt (USGCRP, 2011). Climate vulnerability is uneven across the extent of pinyon–juniper in North America due to the varying magnitude of projected change, the intrinsic sensitivity of human and natural systems in a given place, and their adaptive capacity (Hand et al., 2018). These factors and human interventions will determine how the provision of ecosystem services may be modified.

Pinyon–juniper woodlands, particularly in the southwestern United States, have become hotspots for a changing climate and warmer temperatures (Notaro et al., 2012; Garfin et al., 2013; Thorne et al., 2017). Expected changes include increased summer temperatures and enhanced variability of precipitation and temperature (Seager et al., 2007; Gutzler and Robbins, 2010). Because pinyon–juniper woodlands are inherently moisture-limited they are especially vulnerable to extended drought and higher temperatures (Allen and Breshears, 1998).

Tree Mortality and Plant Composition Changes

Marked change in the distribution and composition of pinyon–juniper systems is anticipated in the coming decades, especially at lower ecotones where conversion to juniper savannahs and grasslands is expected (Allen and Breshears, 1998). Vulnerability forecasts coupled with spatial information on tree density for Arizona and New Mexico (Mellin et al., 2008; Triepke et al., 2019) suggest that shifts are already occurring, with high vulnerability areas seeing a decline in the amount of tree cover and low vulnerability sites remaining on an overall trajectory of increased tree density (Table 2).

Ironically, the woodlands that are forecast to be the most vulnerable to future climate may be the least at risk to mortality from fire (Triepke et al., 2019). There is some evidence indicating that decreased plant productivity from warmer and more arid conditions may be associated with decreased fuel levels and reduced fire risk (Rocca et al., 2014).

The lower warm-dry woodland ecotones of pinyon–juniper communities are inherently vulnerable to periods of warmer temperatures and drought (Allen and Breshears, 1998; Maestas et al., 2016) (Fig. 8). The difference between upper and lower ecotones is reflected by ecosystem resilience in the face of long-term temperature increases that drive the upward expansion of woodlands into montane forest zones and the expansion of grassland and shrubland systems into areas previously occupied by woodlands (Clifford et al., 2011).

It stands to reason that warmer temperatures likewise favor changes in woodland understory vegetation, including trends in shifts from C3 to C4 grasses with increasing aridity. In addition to tree mortality, summer heat events have resulted in widespread mortality of many species of grasses, shrubs, and even cacti (Allen, 2007). Climate controlled changes in overstory and understory vegetation composition and plant productivity ultimately impact ecosystem and human communities that rely on the services of pinyon–juniper.

Carbon Storage as an Ecosystem Service

Vegetation biomass is an integral component of woodland carbon cycling. Through the process of photosynthesis atmospheric carbon dioxide is converted to carbohydrates as *carbon fixation* (Archer, 2011). Carbohydrates are used by plants to grow both belowground tissue in the form of roots and tubers and aboveground tissue in the form of stems and leaves. These components together with standing dead vegetation, downed woody debris, and the litter-duff surface make up woodland *biomass*, about half of which is *carbon stock* (USDA Forest Service, 2015). In pinyon–juniper woodlands there are approximately three to 55 metric

Table 2 Chi-square test evaluating the relationship of tree density and projected climate vulnerability, where high-vulnerability areas reflect less tree cover in comparison to background levels and low-vulnerability areas express greater tree cover.

Tree density	Deviation from expected		Sample number and significance
	Low vulnerability	High vulnerability	
<i>All Pinyon–Juniper</i>			
Stands with low tree cover (10%–29.9%)	–9.6%	12.1%	$n = 255,047$
Stands with high tree cover (30%+)	10.7%	–13.5%	$P\text{-value} < .00000$
<i>Juniper Grass (savannah)</i>			
Stands with low tree cover (10%–29.9%)	–17.6%	2.0%	$n = 19,143$
Stands with high tree cover (30%+)	38.2%	–4.4%	$P\text{-value} < .00000$
<i>Pinyon–Juniper–Evergreen Shrub</i>			
Stands with low tree cover (10%–29.9%)	–11.5%	9.5%	$n = 89,233$
Stands with high tree cover (30%+)	9.8%	–8.2%	$P\text{-value} < .00000$
<i>Pinyon–Juniper with Grass</i>			
Stands with low tree cover (10%–29.9%)	–15.5%	14.3%	$n = 40,367$
Stands with high tree cover (30%+)	14.2%	–13.0%	$P\text{-value} < .00000$
<i>Pinyon–Juniper Persistent Woodlands</i>			
Stands with low tree cover (10%–29.9%)	–2.0%	6.4%	$n = 98,286$
Stands with high tree cover (30%+)	2.8%	–8.8%	$P\text{-value} < .00000$
<i>Pinyon–Juniper with Sagebrush</i>			
Stands with low tree cover (10%–29.9%)	–28.6%	34.0%	$n = 8018$
Stands with high tree cover (30%+)	24.1%	–28.7%	$P\text{-value} < .00000$

**Fig. 8** Conceptual model showing the variation in ecosystem resilience to stress between upper and lower ecotones according to aridity, elevation, and soil properties. The middle line is the resilience as related to elevation and moisture, whereas the upper and lower lines show adjustments for aspect and soil properties. Adapted from Maestas, J., Campbell, S., Chambers, J., Pellant, M. and Miller, R. (2016). Tapping soil survey information for rapid assessment of sagebrush ecosystem resilience and resistance. *Rangelands* **38**, 1–9.

tons per hectare of biomass carbon depending on the type of pinyon–juniper and the stage of succession (Fernandez et al., 2013; Weisz et al., 2010). Soil organic carbon makes up an additional 40–85 metric tons per hectare depending on soil type (Strenger et al., 2007). The amount and kind of soil organic carbon represents and controls soil development and woodland productivity (Van Cleve and Powers, 1995). Carbon can be conversely released from these woodlands to the atmosphere through decomposition and burning. Pinyon–juniper woodlands provide an important carbon storage service by their considerable extent, biomass, and soil reserves which are constantly changing through natural succession and disturbance.

As implied by the discussion on woodland expansion and ingrowth, the balance of carbon stock has increased significantly in pinyon–juniper (Strand et al., 2008; Neff et al., 2009; Fernandez et al., 2013) despite localized carbon losses linked to tree dieback, woodland clearing, stand replacement fire, and erosion. Carbon increases are the likely result of fire suppression and are especially concentrated in fire-adapted types. Trends in the levels of soil organic carbon are mostly influenced by the growth of vegetation, by activities that remove biomass from the soil surface, and by climatic factors of temperature and moisture that influence weathering and decomposition. Causes of carbon loss from woodland soils include fire and erosion from grazing, land conversion, and development. Losses in woodland vegetation cover coupled with climate-induced increases in the intensity of rain lead to reductions in soil aggregate stability and an increase in erosion rates (Allen and Breshears, 1998). For the moment, land use patterns and carbon accumulation appear to be offsetting the effects of climate forcing on the reduction in woodland extent and density (Table 2). There is some debate on the probable effects of 21st-Century climate on decomposition rates and the stability of soil organic carbon (Davidson and Janssens, 2006). But the net effect of climate forcing and land use on pinyon–juniper may be continued increase in total carbon storage.

Conclusion—Climate and Carbon

Increasing temperatures and drought conditions in the interior western United States will likely lead to further tree mortality in woodlands, in turn affecting disturbance processes of soil erosion, insect outbreaks, fire, and additional mortality (Allen, 2007). Climate vulnerability forecasts for pinyon–juniper woodlands in North America (e.g., Comer et al., 2012; Rehfeldt et al., 2006; Triepke et al., 2019) likewise infer vulnerability to plant and wildlife habitat along with risks to provisioning services including pinyon nut production, livestock grazing, and fuelwood.

Future Trends and Conservation

Because P-J woodlands are so extensive in the western United States and northern Mexico, significant efforts are being made to install effective management prescriptions to meet the challenges of conserving biodiversity and natural resources in a rapidly changing world (Aldon and Shaw, 1993; Gottfried et al., 2008). Given increasing frequency of droughts, fire, insect outbreaks, and changes in resource use and management, managers are faced with complex scenarios in their attempt to maintain P-J woodlands in optimal conditions. For example, pinyon jays (*Gymnorhinus cyanocephalus*) have a range that is strongly tied to P-J woodland distribution (across all that shown in Fig. 1 with some minor extension into neighboring forest biomes), but despite their wide range their numbers are significantly declining (Boone et al., 2018). Management strategies implemented to uniformly increase fire frequency across all types through tree thinning or the mechanical treatment to create more open, grassy stands for grazing coupled with increased tree die-off caused by droughts and insect outbreaks may be collectively altering the woodland structure that may be driving downward trend in species populations. This type of scenario likely applies to other animals and plants, each with their unique niche, and where there competing needs for biodiversity and society that managers must address. Looking to the future there is a growing awareness that an integrated ecosystem management approach will increasingly be needed to solve these issues at site to landscape scales across this widely distributed and diverse ecosystem.

Abstract

The vegetation named Mexical inhabiting areas with warm wet summers and dry winters represents the same vegetation associated to Mediterranean climates, characterized to share common characteristics such as evergreen sclerophyll leaves and the ability to resprout after fires. Preliminary evaluations indicate that this vegetation occupies at least 1.8 million of hectares in Mexico, distributed along the rain-shadowed mountain chains of the country, at elevations between oak and pine forests (above), and the xerophytic communities (below). We present a synthesis focusing on historical, paleobotanical and palaeoecological analyses showing that Mediterranean type ecosystems and the Mexical, have a common origin. The archetypal evergreen sclerophyllous vegetation of modern Mediterranean-type vegetation is relictual of the Madrean-Tethyan vegetation of the Paleogene and Neogene periods, which originally existed in a belt around North America and Eurasia when the climate was warm and wet. During a general palaeoclimatic trend towards greater aridity, the Mediterranean climate appeared in the Quaternary when summer precipitation decreased because the oceans became colder and the lands became hotter. The change from tropical to Mediterranean climate led surviving taxa to seek refuge in today's current Mediterranean areas, whereas Mexical did not experience this climatic transition and refuted along the principal mountain chains of Mexico. All these historical effects have been the basis for the analyses about plant ecophysiological studies mostly related to the water economy of evergreen species inhabiting semiarid environments; regeneration niche and community organization; and fire responses of Mexical species. Based on these studies we propose different areas for future research.

Introduction

The Mexical Shrubland and its Similitude with the Mediterranean Shrublands

Plant species assemblages from four continents of the world have traditionally been pointed out to share common characteristics such as evergreen sclerophyll leaves and the ability to resprout after fires (Barbour and Minnich, 1990). This is the case of Mediterranean ecosystems inhabiting areas with warm, dry summers and cool, wet winters (Rundel et al., 2016). These ecosystems constitute iconic examples of hotspots of biodiversity, as they occupy ca. 5% of the Earth's surface, but harbor almost 20% of the known vascular plant species of the world (Cowling et al., 1996). The vegetation in these ecosystems are constituted by evergreen sclerophyllous species, mostly low-stature shrubs and trees (1–3 m high) and broad-leaved species with 40 to more than 100% coverage by woody vegetation. Distributed in five different Mediterranean regions of the world, these ecosystems have been named “maquia” in the Mediterranean basin, “mallee” in the south and south-western Australia, “chaparral” in California, “fynbos” in the Cape Province of South Africa, and “matorral” in Chile (Cody and Mooney, 1978).

Since the 1970s, their study was marked by the convergent model of Mooney and Dunn (1970) generating a fruitful research program in the different Mediterranean areas of the world. Accordingly, the similarities in the characteristics of plant species living in such distant areas would be explained by invoking common adaptations to the Mediterranean climate, high frequency of periodic fires, drought, high temperatures, rainfall unpredictability, and soil oligotrophy (Mooney and Dunn, 1970; Cody and Mooney, 1978; but see Lloret et al., 1999; Verdú, 2000).

However, since the 1930s, different reports of evergreen sclerophyllous vegetation sharing the same or congeneric species with similar “convergent” traits were reported for different parts of Mexico under a tropical climate of summer rains (Muller, 1939, 1947; Shreve, 1939; Le Suer, 1945; Miranda, 1948, 1952; Martin, 1958; Miranda and Hernández, 1963; Rojas-Mendoza, 1965; Rzedowski,

1966, 1978; Rzedowski and Mac Vaughn, 1966; González-Quintero, 1968; Puig, 1970; Axelrod, 1975, 1989; Quero, 1977; Cruz-Cisneros and Rzedowski, 1980; Hiriart, 1981; García, 1983; Valiente-Banuet et al., 1998; Rivera-Hernández et al., 2019). Moreover, the presence of “convergent” plant traits were reported from sclerophyllous taxa in areas of summer and winter precipitation in Arizona-New Mexico, and eastern Mediterranean; as well for summer rain and winter drought in eastern Mexico and northwestern India, as well as in the northern coast of Turkey where rainfall is well distributed throughout the year (Axelrod, 1975). Moreover, the studies of Vankat (1989), in which different responses in seasonal patterns of stem-water potentials for plants inhabiting Arizona (with summer rainfall) and California chaparrals; and the assessment of the degree of convergence among the different Mediterranean-type ecosystems (Barbour and Minnich, 1990) were the basis to claim for a revision of the Mooney and Dunn’s (1970) long-standing paradigm.

Sclerophyllous vegetation under tropical climate in Mexico, named Mexical to differentiate from the Mediterranean vegetation, was described by Valiente-Banuet et al. (1998) showing that species that comprise this vegetation type have many similar characters to vegetation from Mediterranean climate areas. These authors hypothesized that the presence of Mexical, sharing “convergent” traits could respond to historical processes that occurred since floristic elements evolved during the Paleogene, when climate was warm and wet and later on when climate changed since the Oligocene when climatic deterioration with cooler and dryer conditions prevailed until present (Axelrod, 1958, 1975). This initial study (Valiente-Banuet et al., 1998) expanded the convergence paradigm of the chaparral under a more integrative view, in which biogeographic, paleobotanical, and ecological patterns might explain floristic, adaptive, and community organization processes occurring in these environments.

In this article we present a synthesis of these different aspects centered in the Mexical shrubland focusing in: (1) a historical paleobotanical and palaeoecological analysis about its origin and its relationship with the Mediterranean type ecosystems, (2) current geographical distribution; (3) floristic composition and plant traits in order to test whether the characters at the community and population level that have been claimed to converge under Mediterranean climates all over the world are the same as those in these plant communities, as well as a comparative analysis of vegetation across Mediterranean regions, including Mexical, in order to compare between historical and convergence hypotheses (i.e. common history of Paleogene and Neogene taxa vs. adaptations evolved under Mediterranean climates in Quaternary taxa); (4) plant ecophysiological studies mostly related to the water economy of evergreen species inhabiting semiarid environments; (5) regeneration niche and community organization; (6) fire responses of Mexical species; and (7) areas for future research.

Palaeobotanical and Palaeoecological Evidence and the Origin of the Mexical Shrubland

The evolution of Mediterranean-type ecosystems is well studied (Axelrod, 1958, 1975; Palamarev, 1989; Herrera, 1992; Keeley, 1992; Cowling et al., 1996; Ackerly, 2003; Verdú et al., 2003; Rundel et al., 2016). As in other ecosystems, Mediterranean-climate communities are the result of historical effects and sorting processes occurring in different geological times and different ecological scenarios (Herrera, 1992; Verdú et al., 2003; Valiente-Banuet et al., 2006). Many extant taxa in Mediterranean climates originated in the Paleogene and the Neogene (66 to 2 million years (Myr) B.P.) (Axelrod, 1975; Cowling et al., 1996) and are now mixed with recent taxa that evolved at the end of Neogene and the beginning of the Quaternary (2 Myr B.P., post-Pliocene) during a period when global climate became much more arid and cooler (Verdú et al., 2003). In fact, the current Mediterranean climate emerged during the Quaternary (see Rundel et al., 2016), corresponding with the extinction of a substantial component of Paleogene and Neogene taxa, but also providing a strong stimulus for the evolution of new taxa. Based on paleobotanical evidence (Axelrod, 1975; Palamarev, 1989), the archetypal evergreen sclerophyllous vegetation of modern Mediterranean-type vegetation is relictual of the Madrean-Tethyan vegetation of the Paleogene and Neogene, which originally existed in a belt around North America and Eurasia where the climate was wet and warm. Relictual Madrean-Tethyan taxa, or the Laurisilva, can be observed today in the isolated northern Atlantic Canary archipelago (Axelrod, 1975; Juan et al., 2000), and preliminary observations indicate that it can be observed also in different forests of Oaxaca, Mexico, which allows visualizing the magnitude of the occurred climatic change when these forests shifted to shrublands in the transition from Neogene to Quaternary. During most of the Paleogene/Neogene, sclerophyllous shrubs constituted the understory of a rich oak-laurel-madrone woodlands, and these shrubs expanded geographically in response to the drying climate during the transition between the Eocene (55 Myr B.P.) and the Oligocene (36 Myr B.P.) (Axelrod, 1975; Palamarev, 1989). Despite the wave of extinctions that occurred with increasing cooling and aridity, the fossil record shows that large taxonomic components of this ancient flora remained in contemporary communities of Mediterranean regions (Axelrod, 1975; Palamarev, 1989; Herrera, 1992), as well as in tropical non-Mediterranean regions (Valiente-Banuet et al., 1998; Flores-Hernández et al., 1999; Verdú et al., 2003) around the world and include some of the most abundant modern genera. This is the case of the Mexical located in the Tehuacán-Cuicatlán Valley, in which floristic elements such as *Rhus*, some Rosaceae, *Quercus*, and *Fraxinus* have been reported for the Tehuacan Formation of Middle Miocene by Ramírez-Arriaga et al. (2014).

According to Herrera (1992), pre-Pliocenic and Quaternary taxa of the Mediterranean Andalusian vegetation differ substantially in life-history-reproductive traits showing that these differences have a strong historical component that was set before the Mediterranean climate appeared. Similarly, Verdú et al. (2003) analyzed pre-Pliocenic and Quaternary taxa in the Mexical showing two contrasting life-history and reproductive traits of woody genera. Mexical did not experience a climatic transition from tropical to Mediterranean climates because it has always been in a tropical climate (Raven, 1973; Rzedowski, 1978).

Both studies agree that the most important traits distinguishing old and Quaternary syndromes are fruit type (fleshy vs. non fleshy fruits) and seed size, which are directly related to the regeneration niche. By integrating biogeographic, paleobotanical, and ecological relationships among species in these plant communities, Valiente-Banuet et al. (2006) showed that during recruitment, facilitative ecological interactions among plant species depend on the evolutionary histories of taxa (periods and environment in which species evolved). Thus, facilitation, as a positive interaction in which one species enhances the establishment of other species and no harm is caused to either; or even possibly being a mutualism (Stachowicz, 2001), is much more important

Fig. 1 Regeneration-niche requirements of Tertiary (Paleogene and Neogene) and Quaternary lineages, based on the fossil record, in the five Mediterranean areas of the world and in the Mexical shrubland of central Mexico. Filled bars show the observed numbers of species from each lineage reported in the literature that occupy particular regeneration niches, and open bars show the expected numbers of species of each lineage. Copyright (2006) National Academy of Sciences, U.S.A.

for the recruitment of species that evolved in the Paleogene and Neogene periods than for the recruitment of species that evolved in the Quaternary period (Fig. 1). In sum, modern regeneration niches and recruitment life history strategies of taxa derived from the ancient Madrean-Tethyan flora and the recent Quaternary are highly correlated with the time and environment in which these taxa evolved. This can be seen during succession in which Quaternary species are the most common early colonizers of open areas in Mediterranean climate vegetation (see supporting information Table 2 in Valiente-Banuet et al., 2006). In contrast, most late successional species identified in the literature were pre-Pliocene elements. These patterns are reinforced by experimental facilitative studies (Gómez-Aparicio et al., 2004), which demonstrated that pioneer (i.e., Quaternary) shrubs facilitate the establishment of woody, late-successional (i.e., pre-Pliocene) Mediterranean species. Likewise, old lineages seldom recruit by seed in the first several decades after fire, and, therefore, these taxa require long fire-free periods for establishment, which occur almost exclusively after closed-canopy stands have developed (Keeley, 1992). Once prepliocenic elements dominate the vegetation seedling establishment use to occur through facilitation among these old lineage elements. All this evidence supports the idea that species which evolved under more mesic environments than today require facilitation for establishment, suggesting that facilitation mimics the Paleogene/Neogene niche, a process that played a crucial role in maintaining biological diversity through evolutionary time (Valiente-Banuet et al., 2006). In other words, community-scale facilitation appears to have been a crucial historical sorting process sustaining ancient species in semiarid plant communities as the globe became more arid (Valiente-Banuet et al., 2006). This regeneration niche conservatism is a central aspect to analyze community assembly processes in these ecosystems (see the niche conservatism and community organization processes section below).

Geographical Patterns of the Mexical

The distribution of the Mexical is concentrated along the mountain chains of Mexico (Fig. 2), occupying an intermediate position between oak and pine forests (above), and the xerophytic communities (below), although in many cases it occupies the mountain-tops. Altitudinally the Mexical ranges between 1800 and 2800 m.a.s.l. Climatically, the Mexical ranges from arid to dry-temperate climates, which corresponds to types Bs and Cw, respectively (García, 1988). Its distribution includes the states of Aguascalientes,

Fig. 2 Distribution of the Mexical (red-dotted marks) under wet-summer climates in México. The yellow-delimited zone in the North West of Mexico indicates the chaparral distribution under Mediterranean climate.

Baja California Sur, Coahuila, Chihuahua, Durango, México, Guanajuato, Guerrero, Hidalgo, Jalisco, Nuevo León, Oaxaca, Puebla, Querétaro, San Luis Potosí, Tamaulipas, Tlaxcala, and Zacatecas (Figs. 3–5). In all cases, the Mexical is located along the dry (rain-shadowed) aspects of different mountain chains including the Sierra Madre Oriental, Sierra Madre Occidental, Neovolcanic belt, and Oaxacan mountains.

Floristic Composition, Vegetation, and Plant Traits of Mexical

Floristically, the Mexical shrubland shares common genera with all the Mediterranean shrublands. For example, some of the genera of the Mexical have the same species or close relatives of those present in the Californian Mediterranean ecosystem (i.e., *Arbutus*, *Ceanothus*, *Garrya*, *Juniperus*, and *Rhus* (Table 1). In addition, the Mexical share common genera with the Mediterranean ecosystems of Chile, the Mediterranean Basin, or Australia (i.e., *Acacia*, *Gochnatia*, *Baccharis*, *Satureja*, *Rhus*, *Juniperus*, *Arbutus*, *Comarostaphylis* (= *Arctostaphylos*), *Quercus*, *Pistacia*, *Salvia*, *Stevia*, *Lithospermum*, *Linum*, *Aristida*, *Dodonaea*, etc. (Valiente-Banuet et al., 1998). A summary of floristic composition of different studies conducted in Mexico, shown in Table 2, indicates that mexical shrubland occupies altitudes ranging between 1800 and 2800 m.a.s.l. with many common genera and species among the different localities, being Anacardiaceae, Fagaceae, Rosaceae, Asteraceae, Ericaceae, and Fabaceae, the most well represented taxonomic families.

Based on floristic records and field samplings in two localities of the Tehuacán-Cuicatlán Mexical (Fig. 2), Valiente-Banuet et al. (1998), reported a total of 225 species and plant diversity of 90 ± 6 species of vascular plants per 1000 m² sample in two study zones. Also, from these samplings, they obtained for each woody species information of relative cover, maximum and minimum height, and frequency (%) as the proportion of times each species was found in the 15 lines. From these data the Relative Dominance Index (R.D.I.) per species was obtained, such that $R.D.I. = \text{relative cover (\%)} \times \text{frequency (\%)} \times \text{relative density}$, where relative density = number of individuals in 50 m². They found that the Mexical is a broad-leaved evergreen sclerophyllous shrubland constituted mainly by shrubs (47%), ephemerals (39.2%), chamaephytes (10.8%) and trees (7.41%). In both cases plant coverage ranged from 105 to 187% (Table 3), although many areas in which soils present a well-developed petrocalcic horizon plant cover is ca. 40–60%.

Also, a comparative analysis of plant characters of the dominant woody species from different Mediterranean areas and the Tehuacán-Cuicatlán mexical was conducted by Valiente-Banuet et al. (1998). To do so, information from Mediterranean areas were obtained from the Specht (1988) databook. The importance of the species within their studied communities was confirmed from studies of Wilson and Vogl (1965), Hanes (1977), and Mooney et al. (1977) for the Californian chaparral; Mooney et al. (1977) and Rundel (1981) for the Chilean matorral; Beadle (1981) and Specht (1981) for the Australian mallee; and Tomaselli (1981), Quezel (1981),

Fig. 3 Mexical shrubland in the Puebla State, ca. 2000 m elevation. A large number of shrubs and some trees are present and include: *Brahea nitida*, *Amelanchier denticulata*, *Dodonaea viscosa*, *Garrya ovata*, *Quercus sebifera*, *Dasyllirion serratifolium*, among others.

Fig. 4 Mexical shrubland in the Oaxaca State, ca. 2200 m elevation. A large number of shrubs and trees are present and include: *Amelanchier denticulata*, *Dodonaea viscosa*, *Fourcraea* sp., *Garrya ovata*, *Quercus obtusata*, *Comarostaphylis polifolia*, *Opuntia* sp., among others.

and Romane and Terradas (1992) for the Mediterranean Basin vegetation of France, Spain, and Greece (Valiente-Banuet et al., 1998). Fourteen characters regarding plant form, photosynthetic organs, and leaf characteristics characterizing typical Mediterranean traits were used in the comparative analysis (Table 4). The role of the characters was weighted by means of the number of species scored in each area and then ordinated by a Simple Correspondence Analysis (Valiente-Banuet et al., 1998). As a reference, the spiny shrubland vegetation adjacent to mexical was considered in the analysis, which is distributed close to the mexical, with an altitude ranging from 1380 to 1800 m.a.s.l. (Valiente-Banuet et al., 2000) and an average annual rainfall around 425 mm (Dávila et al., 1993; Valiente, 1991). The inclusion of this external group into the analysis was considered to test the similarity with the mexical situated within the same region and just below the altitudinal belt of the sclerophyllous vegetation. A total of 121 dominant species were included in the analysis: 28 for the Tehuacán region, 18 for the Tehuacán spiny shrubland, 23 for the Californian chaparral, 13 for the Chilean matorral, 24 for the Mediterranean Basin, and 15 for the Australian mallee. The correspondence analysis showed two different groups (Fig. 6). The first corresponds to the areas of evergreen sclerophyllous vegetation (Chilean matorral, Tehuacán mexical, Californian chaparral, Australian mallee, and Mediterranean Basin vegetation) and the second to the Tehuacan spiny shrubland. Both groups were differentiated on the basis of leaf seasonality, consistency, and angle. In all five evergreen sclerophyllous vegetation areas of the analysis, the character states “evergreen” and “sclerophyllous” and “vertical leaf angles” were dominant. In contrast, in the

Fig. 5 Mexical shrubland in the Tamaulipas States in North East Mexico, ca. 2000 m elevation. A large number of shrubs and trees are present and include: *Rhus virens*, *R. chondroloma*, *R. pachyrrhachis*, *Garrya ovata*, *Quercus* spp., *Pinus* sp.

Modified from Valiente-Banuet, A., Flóres-Hernández, N., Verdú, M., and Dávila, P. (1998). The chaparral vegetation in Mexico under non-Mediterranean climate: Convergence and Madrean-Tethyan hypotheses reconsidered. *American Journal of Botany* 85, 1398–1408. Rights Link License Number: 4638360309620.

Tehuacan spiny shrubland the character states “deciduous,” “malacophyllous,” and “horizontal leaf angles” were the dominant traits. Two of these discriminatory characteristics (evergreen and sclerophyllous) correspond to those found by Barbour and Minnich (1990) as consistently similar among the five Mediterranean-type ecosystems. The other factor, steep leaf angles, has been reported as an adaptation of Mediterranean sclerophyllous plants to reduce radiation absorption during extended drought periods (Ehleringer and Comstock, 1989; Valiente-Banuet et al., 2010). Considering the second axis in the correspondence analysis, the number of stems is a significant discrimination factor. This character can be considered as an architectural characteristic related to resprouting ability, and is represented by a significant number of species in the Chilean matorral not so frequently observed in other Mediterranean regions. Mediterranean-type ecosystems have been matched with natural fires and therefore typical features of shrubs, such as

Table 2 Environmental and vegetation characteristics of Mexical under wet-summer climates.

lignotubers and burls at the root crown/stem base, have been associated with postfire resprouting ability (James, 1984; Kummerow and Ellis, 1989). These woody structures and resprouting ability are present in the shrubs of the Tehuacan mexican where there is no evidence of periodic fire, indicating that their presence can be better considered as an ancient preadaptation to fire inherited from ancestors belonging to laurophyllous forests (Axelrod, 1975).

Trait similarity not only among plant species from different Mediterranean ecosystems but also from Mexical species challenged the convergence hypothesis. [Verdú et al. \(2003\)](#) showed that the similarities among Mediterranean (including Mexical taxa) were explained by common ancestry because similarities in the character syndromes vanished when common genera were excluded from the analysis.

Plant Physiological Studies

Limited water represents a major stress affecting plant performance within both Mediterranean-type and Mexical ecosystems. Since leaf temperatures usually increase plant water stress, steep leaf angles contribute to a reduction in leaf solar radiation absorption (Smith and Ullberg, 1989) (Fig. 7). Functionally, the predominance of steeply inclined foliage in water-limited environments has been considered as a strategy to cope with water limitations and high radiation loads (Falster and Westoby, 2003). Steep leaf angles with respect to the horizontal plane considerably reduce heat loads particularly at midday, decreasing the risk of over-heating and photoinhibition (Valladares and Pugnaire, 1999). Likewise, species with steep leaf angles may be able to maintain increased levels of photosynthesis during high radiation periods (Falster and Westoby, 2003) increasing water use efficiency (King, 1997). Different studies have considered that such leaf architecture may have adaptive value in arid environments due to its positive effects on reproduction output (Smith and Ullberg, 1989; Pearcy et al., 2005). In the Tehuacan mexical, 93% of the species present leaf angles ranging between 45 and 90 degrees with respect to the horizontal axis, which suggests that evergreen-sclerophyllous species are responding mainly to water stress. Valiente-Banuet et al. (2010) quantified leaf angle in 28 dominant species under a phylogenetic framework and evaluated the functional implications of the observed range of leaf angles in terms of leaf temperature, water potentials, and transpiration. In addition, they combined manipulative experiments restraining leaves horizontally with microclimatic and stomatal conductance measurements in five species. Leaf angles were experimentally manipulated to restrain leaves horizontally by inserting an inert epoxy material between the leaf petiole and the branch. A control branch of the same height and with a similar number of leaves as the experimental branch was labeled on the same individual. In all cases, branches with horizontally restrained leaves presented significantly lower water potentials than control branches in all of the five species studied: *Citharexylum oleinum* (Verbenaceae), *Comarostaphylis polifolia* (Ericaceae), *Garrya ovata* (Garryaceae), and *Quercus sebifera*. Because phylogenetic analyses showed that steep leaf angles evolved in a correlated fashion in evergreen species, they concluded that it is an adaptive trait allowing evergreen species to cope with dry conditions to persist within the mexical community.

Fig. 7 *Arctostaphylos pungens* in the Tehuacán-Cuicatlán Mexican showing its almost vertical leaves.

A comparative study between the California chaparral and the Mexical shrubland was conducted by Bhaskar et al. (2007) to analyze the adaptive significance of traits governing plant water use. By comparing closely-related species pairs in these two geographic localities, they examined whether evolutionary contrasting divergences in hydraulic conductivity were associated with contrasting seasonality of the rainy season. Evolutionary correlations were examined also by using phylogenetically independent contrasts, considering a suite of hydraulic traits, including stem and leaf specific conductivity, resistance to embolism, wood density, inverse Huber value, and minimum seasonal water potential. Despite the seasonal climatic differences between California and Tehuacán (high summer temperatures and high vapor pressure deficit in the former, and summer rain regime and annual period of soil water deficit coinciding with the cooler months in the latter), predrawn water potentials at the end of the dry season did not differ between localities. In addition, although evolutionary divergences in hydraulic traits among the selected species pairs were expected to be correlated with the precipitation conditions at each locality, sapwood specific conductivity (K_s), did not differ between sites. In contrast, leaf-specific conductivity was higher in California which may be adaptive where soil and atmospheric droughts coincide during summer. Finally, a significant correlation was found between divergencies in xylem resistance to embolism and minimum seasonal water potential, but surprisingly, no evolutionary trade-off was found between resistance and stem conductivity.

Plant Phenology

Plant phenology in Mediterranean type ecosystems is also a trait that had been hypothesized to have converged under the selective pressure imposed by the typical summer stress (Mooney and Kummerow, 1981). In contrast, Mexical shrubland has not experienced summer drought because of its tropical climate. While spring flowering is the typical phenology of Mediterranean plants, nonseasonal flowering is typically produced in tropical communities. To test the weight of the evolutionary history in the phenological response of plants to climatic conditions, Verdú et al. (2002) compared flowering phenology of Mexical plants to that of Mediterranean ecosystems. Flowering phenology in the Mexical strongly differed from that of Mediterranean ecosystems because it was not as seasonal and the flowering peak was produced in summer. Phenological differences were not only shown at the community level but also between Mexical and their Mediterranean congeneric species. These findings suggest that despite sharing common ancestors, current climatic conditions drive different phenologies. At what extent such phenological response is a product of plasticity deserve further research (see Vanderplank and Ezcurra, 2015).

Regeneration Niche Conservatism and Community Organization

The growing evidence that closely related species with disjunct distributions have maintained their fundamental niche features through evolutionary time (Wiens and Graham, 2005) supports the hypothesis that the niche evolves in a conserved manner. This pattern, known as phylogenetic niche conservatism constitutes a central aspect for understanding the mechanisms that organize communities (Wiens and Graham, 2005; Valiente-Banuet and Verdú, 2007). Actually, interspecific interactions that comprise a substantial part of the species niche, and the organization of biological systems through evolutionary time is mediated by a marked conservatism of ecological interactions across the entire Tree of Life (Gómez et al., 2010). On this vein, Valiente-Banuet et al. (2006) hypothesized that there should be a correlation between the characteristics of the environment in which individual taxa evolved and the contemporary features of the regeneration niche of these species. They found that in Mediterranean climate and Mexical communities most woody Paleogene/Neogene floristic taxa tend to recruit through facilitation, whereas Quaternary elements do it in open spaces. As a way to test whether regeneration niche evolves in a conserved manner, Valiente-Banuet and Verdú (2007) analyzed the regeneration niche in a large worldwide database in which Mediterranean and Mexical taxa were included and shown to be strongly conserved (Valiente-Banuet and Verdú, 2007). The salient picture of regeneration niche conservatism is that nurse species facilitate distantly related species, suggesting that at the community level, facilitation increases the phylogenetic diversity of the plant community. This hypothesis has been already tested in Mediterranean Basin shrublands (Verdú et al., 2009) and in Mediterranean Basin grasslands (Soliveres et al., 2012) showing that effectively, facilitation occurs between distantly related species

and that observed phylogenetic distance between nurses and facilitated species were significantly higher than the expected from a null expectation in the community (Valiente-Banuet and Verdú, 2013).

Fire Responses of Mexical Species

In Mediterranean-type ecosystems, fire has been recognized as an important factor determining vegetation dynamics (Hanes, 1971; Moreno and Oechel, 1994). Regenerative mechanisms that allow populations to recover after fire are widespread in Mediterranean-type vegetation (Mooney and Dunn, 1970; Keeley and Zedler, 1978; Gill, 1981; Trabaud, 1987). For example, these mechanisms include fire-stimulated germination, or resprouting from stumps, lignotubers, or burls (James, 1984). For obligate seeders, fire has been proposed as a major selective force leading to the acquisition of this character associated with post-fire regeneration (Gill and Groves, 1981; Keeley, 1986). The hypothesis of the adaptive significance of resprouting due to recurring fire (Mooney and Dunn, 1970; Biswell, 1974; Naveh, 1975; Shmida, 1981) has often been rejected because the resprouting habit is common among the dicotyledons, and several authors have proposed resprouting to be a preadaptive character resulting from anatomical features and herbivory pressures (Trabaud, 1987; Zedler and Zammit, 1989; López-Soria and Castell, 1992; Lloret et al., 1999).

In the Mexical, fire in the past has been absent or very rare (Valiente-Banuet et al., 1998). However, in the last decades, some human-caused fires have occurred but in the last few years, this type of disturbance has increased its frequency in different parts of Mexico as a consequence of long drought periods. Consequently, it is important to know the ability of these communities to regenerate after burning (Lloret et al., 1999). Valiente-Banuet et al. (1998) reported plant responses after a fire occurred in the Mexical shrubland in south-central Mexico. In June 1995, a wildfire burned 2 ha of mexical shrubland in Cerro Viejo mountain (Mexico, Tehuacán Valley, 18°15' N, 97°26' W; 2450 m.a.s.l.). In April 1997, five 25 × 2 m transects were established and all stump diameters of dead and resprouting plants for each species were measured (Valiente-Banuet et al., 1998). A total of 14 species resprouted: *Ageratina spinosarum* (Asteraceae), *Amelanchier denticulata* (Rosaceae), *Comarostaphylis polifolia* (Ericaceae), *Citharexylum oleinum* (Verbenaceae), *Croton hypoleucus* (Euphorbiaceae), *Gochmatia smithii* (Asteraceae), *Havardia elachystophylla* (Mimosaceae), *Lindleya mespiloides*, *Quercus sebifera* (Fagaceae), *Rhus standleyi*, *Rhus virens* (Anacardiaceae), *Salvia aspera*, *Salvia candicans* (Lamiaceae), and *Xerospirea hartwegiana* (Rosaceae). Reproduction from seeds was recorded only for *Croton hypoleucus*, *Gymnosperma glutinosum* (Asteraceae), *Ceanothus greggii* (Rhamnaceae), and *Phytolacca icosandra* (Phytolaccaceae).

Moreover, an experimental study on the resprouting response to fire that considers the development stage of the plants and the biogeographical origin of the species was conducted by Lloret et al. (1999) in the Tehuacán-Cuicatlán mexical. A total of 24 plants of eight dominant species were selected at Cerro Zotaltepec (Mexico, Tehuacán-Cuicatlán Valley (Fig. 2; 18°38' N, 97°27' W; 2350 m a.s.l.). Four of these species which belong to relict genera of the Madro-Tertiary Geoflora, with close relatives in the Californian chaparral were able to resprout after fire (Axelrod, 1975; Valiente-Banuet et al., 1998) (*Quercus sebifera*, *Rhus standleyi*, *Garrya ovata*, and *Comarostaphylis polifolia* subsp. *polifolia*). In contrast, the other four species, *Xerospirea hartwegiana*, *Coutaportia ghiesbreghtiana*, *Mortonia diffusa*, and *Krameria cytisoides*, having Neotropical affinities (Rzedowski, 1978; Gentry, 1982; Henrickson, 1985; Maberley, 1997) showed less ability to regenerate after fire, and small plants were more likely to die after disturbance than in the Madro-Tertiary group. They found that resprouting is a widespread trait in the Mexical species characterized by the presence of lignotubers and burls. Resprouting can be considered an ancient trait, probably linked to losses of aboveground biomass, that became a preadaptation in Mediterranean fire-prone communities. They concluded that the resprouting feature and the seeder strategy of other species after a fire in the Mexical shrubland are similar to Mediterranean-type ecosystems, emphasizing their common origin and the relevance of phylogenetic and biogeographical studies to explain current patterns of vegetation.

Areas for Future Research

Undoubtedly, Mexical shrubland is the least studied ecosystem of Mexico. Accordingly, complete biodiversity studies are needed in order to assess the Mexical contribution to the world's biodiversity considering its closeness to the tropics. As we have pointed out, the study of the Mexical shrubland under a more integrative approach, including biogeographic, paleobotanical, and ecological patterns, has opened the possibility to explain floristic, adaptive, and community organization processes occurring in these environments.

Moreover, pollination studies are needed in relation to the pre-Pliocene syndrome proposed by Herrera (1992) which has been validated for the Mexical by Verdú et al. (2003) and the potential role of bees on pollination success. In addition, no studies have been conducted involving seed dispersal in the Mexical, mostly for the pre-Pliocene floristic elements which depend on facilitation for seedling establishment. All these aspects open the possibility to unravel coevolutionary processes if plant-animal interactors have been interacting for long periods of time.

Finally, global climate change, is an urgent task to consider in the Mexical shrubland. Although it distributes along the principal mountains of Mexico, our observations indicate that in many cases this vegetation occupies the mountaintops. Historical information shows that this vegetation had altitudinal or geographical shifts as a result of the climatic fluctuations occurred in the Southern and Northern hemispheres during the Quaternary (Betancourt et al., 1990; Markgraf et al., 1995), which emphasize its vulnerability to the increase of temperatures and the intensity and duration of droughts. Currently, an increase of severe droughts in Mexico has been documented for the last two decades (Cruz, 2011; Neri and Magaña, 2016; Murray-Tortarola et al., 2018).

Ecophysiologically, most of the Mexical plants that are C3, sclerophyllous and evergreen species will have to deal with the problem that the increase in droughts will pose in terms of low water availability and loss of moisture due to stomatal opening during the day. Accordingly, analyzing the mechanisms of resistance to water stress of these taxa, mainly those related to the susceptibility of embolisms in vascular ducts, is crucial to understand the near future of the Mexical shrubland under the ongoing climate change.

Acknowledgments

The authors thank Tania Sánchez Ortiz and Noé Flores Hernández for the elaboration of figures and tables as well as the search for information to elaborate this article. This work was carried out thanks to the support of the DGAPA-PAPIIT project (IN-210117).

Abstract

The Cerrado Biome is considered one of the most important savanna biomes in the world, due to its high species richness, endemism, and source of multiple valuable ecosystem services. The Cerrado landscape is diverse, with a mixture of open grasslands, shrub lands, open woodland, and closed canopy woodlands as the dominant ecosystems. The region also harbors ecologically important habitats more restricted in area, such as gallery forests, tropical dry forests, marshes, palm groves, and high elevation rocky grasslands, all of these important contributors to the overall diversity of the region. Many of Brazil's most important rivers originate in the Cerrado highlands and plateaus. The Cerrado also is home to a diverse and evolutionary distinctive flora and fauna, with multiple major sub-regions each with distinctive plant and animal species. Some of the diversity is evolutionarily quite old. The Cerrado has recently become a focal region for the expansion of Brazilian agriculture, and vast areas have been modified in the past 50 years. In addition, the population in the region has grown dramatically of the past five decades, placing additional demands on water resources. Although there are a number of important protected areas, the region is still under protected and more conservation effort needs to be applied to the protection of the biodiversity of the Cerrado in order to save this unique global resource.

What Is Cerrado?

The Cerrado covers 2 million km² in central South America (Fig. 1). It encompasses most of Central Brazil (most of Mato Grosso, Mato Grosso do Sul, and Tocantins; western Minas Gerais and Bahia; southern Maranhão and Piauí; all Goiás and Distrito Federal; and small portions of São Paulo and Paraná), northeastern Paraguay (departments of Amambay, Canindeyú, Concepción, San Pedro, and Alto Paraguay) and eastern Bolivia (provinces of Itenez, Guarayos, Ñuflo de Chávez, Velasco, Chiquitos, and Ángel Sandoval). Cerrado is a morphoclimatic domain because it shows a unique combination of geomorphology, geology, soils, vegetation, and climate (Ab'Saber, 1977). Cerrado is an ecoregion when all of these unique biological and ecological features are considered together (Olson et al., 2011). When only species distributions are taken into account, the Cerrado is a dispersal center (Müller, 1973), an area of endemism (Cracraft, 1985; Haffer, 1985), a phytogeographic province (Rizzini, 1976), and a biogeographical province (Cabrera and Willink, 1980; Morrone, 2017; Udvardy, 1975). Cerrado has even classified as a biome for legislation purposes in Brazil (IBGE, 2004), but the use of this term has been criticized in the literature (Batalha, 2011). In overall, there is a general consensus that Cerrado is one of the most distinct South American biogeographic regions regardless of the information and criteria used to demarcate it (Fig. 2).

Cerrado has borders with all major South American lowland biomes (Silva and Bates, 2002): The Amazon (on the north), the Chaco and Pantanal (on the west), Caatinga the (on the northeast), and the Atlantic forest (on the east and the south). As is common in South American biogeography, the boundaries between Cerrado and other major ecological regions are not well defined (Ab'Saber, 1977). Instead, these regions are separated by transition zones where vegetation mosaics create fascinating landscapes found nowhere else. These ecotonal regions have a complex interplay of species from various biomes resulting in a high combined regional species richness and unique communities of species in contact zones (Bezerra et al., 2009; Bueno et al., 2018; Lacher and Alho, 2001).

The Landscapes of Cerrado

The core of Cerrado is located on the large blocks of crystalline or sedimentary plateaus in Central Brazil. The continuity of these plateaus is only broken by a network of peripheral or intermontane depressions (Brasil and Alvarenga, 1989). The flat, gently rolling surfaces of the plateaus (500–1820 m of elevation) were mostly molded from the Upper Cretaceous to the Mid-Tertiary, during the South-American cycle of erosion (Braun, 1971; Cole, 1986). Then, the resulting peneplain (Sul-Americana surface) was uplifted during the Plio-Pleistocene, with associated subsidence leading to the formation of the peripheral depressions, which has altitudes

Fig. 1 The Cerrado Biome is located in Central South America.

ranging from 2 to 600 m (Brasil and Alvarenga, 1989). Peripheral depressions have been continuously transformed during the Quaternary by the most recent cycles of erosion (Braun, 1971). Geomorphological evidence suggests that during the cyclic global climatic fluctuations in the Pleistocene and Holocene, peripheral depressions were much more unstable and prone to ecological changes than the plateaus (Ab'Saber, 1983).

The tops of the plateaus are covered mostly by cerrado *sensu lato* (s.l.), a xeromorphic vegetation that grows on the deep, well-drained, and nutrient-poor soil (Eiten, 1972; Furley and Ratter, 1988). Cerrado s.l. is composed of two layers: a woody layer that includes trees and large shrubs, and a ground layer, which is composed of subshrubs and herbs. The flora of these two layers have possibly different origins, but both are well adapted to poor soils and frequent fires (Rizzini, 1976). There are five structural types for

Fig. 3 Broad savannas on the uplands bordering a stream-side gallery forest. (Photo credit: T. Lacher).

the cerrado s.l. (Eiten, 1972): (a) campo limpo (“clean field”), dry grassland with few or no shrubs or taller woody plants (Fig. 3); (b) “campo sujo” (“dirty field”), grassland with scattered shrubs and small trees (2–3 m tall); (c) campo cerrado (“closed field”), an open scrubland (3–6 m tall) with few trees and a large proportion of grassland; (d) cerrado (sensu stricto), a woodland (3–8 m tall) with closed scrub and more trees but still with herbaceous vegetation between them; and (e) cerradão (“tall cerrado”), a dense woodland (8–15 m tall) that often has a completely closed canopy and a ground layer much reduced (Fig. 4). Soil fertility and fire regime are the two most common factors used to explain the structural variation in cerrado s.l. (Bueno et al., 2018).

In a few places where the ecological conditions in the tops of the plateaus are not suitable for cerrado s.l., other vegetation types are found (Bueno et al., 2018; Eiten, 1972). These are: (1) veredas, valley-side marshes with palm groves of buriti-palm (*Mauritia flexuosa*) that dominates areas with a large fluctuation in the water table; (2) riverine and valley forests, 20–30 m tall semi-deciduous to evergreen forests with a humid understorey that harbors many ferns, epiphytes, as well as palms, and are found on cambisols or hydromorphic soils rich in organic matter along the streams or covering a wide valley floor; (3) seasonally tropical dry forests that grow on a few, small and scattered areas where limestone rocks were exposed due to erosion; (4) campo rupestre (rocky grasslands), a vegetation rich in endemic species that are found in high altitudes on the tops of the ancient plateaus and mountain ridges where soils are shallow.

In contrast with the plateaus, the peripheral depressions are generally flat pediplains associated with the channels of the region’s major rivers (Brasil and Alvarenga, 1989). Because the landscapes of depressions include both the pediplains and the scarps of the plateaus, they are much more heterogeneous than those found on the top of plateaus. As a consequence, peripheral depressions are covered by vegetation mosaics that include riverine forests, seasonally tropical dry forests, cerrado s.l., and grasslands. Riverine forests are found only along with the courses of the large rivers in the Cerrado. They are semi-deciduous to evergreen forests with trees 20–30 m tall. In contrast, seasonally tropical dry forests (“matas secas” in Portuguese) are deciduous or semi-deciduous forests with canopy height averaging 20–45 m that grow on patches of mesotrophic soils derived from basic rocks such as limestone

Fig. 4 Cerradão, the dense high canopy physiognomy associated with deeper soils and higher soil fertility.

(Bueno et al., 2018; Ratter et al., 1978). In some depressions (e.g., the Paran  River valley), tropical dry forests are the dominant vegetation type. Floodplain grasslands are a seasonally flooded vegetation found on areas of flat topography along the large rivers; they can be the dominant vegetation in a depression, such as the ones found in the Bananal Island in the Araguaia River valley.

In addition to terrestrial ecosystems, the Cerrado is home of important freshwater ecosystems (Innoc ncio, 1989). In fact, the Cerrado is the region where some of the longest South American rivers have their headwaters. The rivers and their affluents that originate on the high plateaus of the Cerrado flow to almost all neighboring ecological regions. Among the rivers that have headwaters in Cerrado are the Xingu, S o Francisco, Tocantins-Araguaia, Parna ba, Tapaj s, tributaries to the right margin of the Paran  River and all rivers forming the Pantanal. Little is known about the evolution of the present-day drainage system of the Cerrado Region. It has certainly had a long and dynamic history associated with the geological changes in central Brazilian plateaus since the Paleozoic (Innoc ncio, 1989). However, most of its modern features developed more recently, possibly in association with the Plio-Pleistocene uplift (Brasil and Alvarenga, 1989; Braun, 1971).

The climate of the Cerrado is tropical seasonal. The dry period, from May through September or October, coincides with the coldest months of the year (Nimer, 1989). The average annual rainfall ranges from 759 to 2245 mm, and the average annual temperature from 15.4  C to 27.8  C. Extremes of minimum temperature vary from 4.4  C to 14.7  C whereas extremes of maximum temperature ranges from 23.6  C to 36.5  C. In the context of the ecoclimatic zones of the Earth (Bailey, 2014), the Cerrado is part of the savanna division of the humid tropical domain that includes around 20.6 million km² of South America, Africa, Asia, and Oceania. The degree of seasonality in the Cerrado varies dramatically throughout the biome, with regions closer to the Amazon or Atlantic forest having longer periods with an excess of precipitation over evapotranspiration, generally in October through April (Camargo, 1971). This wetter period is somewhat shorter in the core areas of the Cerrado, and grades to semiarid conditions, with declining surplus of moisture, where the Cerrado grades into the Caatinga of northeastern Brazil. During the dry season grasslands become dry and brown and fire susceptibility increases dramatically. Woody Cerrado vegetation is highly resistant to fires, and many seeds of Cerrado plants have higher germination rates post-fire. A number of other Cerrado plants exhibit post-fire flowering (Miranda et al., 2002).

The Biodiversity of Cerrado

The Cerrado vegetation in Brazil is represented by a core area and a number of disjunct Amazonian Cerrados. There are some clear phytogeographic patterns observed across this vast savanna region (Ratter et al., 2006). The pockets of *Disjunct Amazonian Sites* are located in small isolated regions in the states of Roraima, Amap , and Par , with a more isolated region on the border between Amazonas and Rond nia. These are depauperate and quite distinct floristically. There is another small but distinctive region, *Far-Western Mesotrophic Sites*, in Rond nia located on more mesotrophic soils. The core region of the Cerrado is further divided into four geographic regions which have pronounced heterogeneity in species composition. These four regions, *North and North-Eastern*, *Central and South-Eastern*, *Southern*, and *Central-Western*, all have species restricted to their regions, ranging from 57 of 333 in the North and North-Eastern region to 162 of 557 total species in the Central-Western region (Ratter et al., 2006). These strong phytogeographic patterns contribute to the overall diversity of plants in the Cerrado.

Similar patterns of heterogeneity in species composition across the broad Cerrado landscape are observed in animal groups as well. Lepidopterans (moths and butterflies) show a strong influence of larger landscapes and vegetation on moth community composition, but geographic clustering in butterflies (Brown and Gifford, 2002). The biogeography of birds in the Cerrado is influenced by Amazonian and Atlantic Forest elements, given more mobile birds are able to colonize the Cerrado along the mesic gallery forests of the main Brazilian rivers (Silva, 1995a,b). The Atlantic Forest influence, however, is stronger than that of the Amazon (Silva, 1996). Mammalian species richness in the Cerrado is third in Brazil compared to the Amazon and Atlantic Forest biomes. One of the interesting aspects of the mammalian fauna of the Cerrado is the dominance of small bodied mammals and the low species richness of large grazing herbivores, in contrast to the African savannas (Marinho-Filho et al., 2002).

During the 1970s, the biota of Cerrado was considered as having both a low number of species as well as a low percentage of endemic species. However, intensive field surveys conducted since the 1980s have rejected both hypotheses. To date, scientists have identified in the region 12,097 species of plants (Zappi et al., 2015), 800 of fishes (Mittermeier et al., 2011), 209 of amphibians (Valdujo et al., 2012), 76 of lizards (Nogueira et al., 2011), 158 of snakes (Nogueira et al., 2011), 33 of amphisbaenians (Nogueira et al., 2011), 856 of birds (Silva and Santos, 2005), and 251 of mammals (Paglia et al., 2012). The percentage of endemic species ranges from 3.6% in birds to 60.6% in amphisbaenians (Table 1). Because large areas of Cerrado have never been sampled for any group of organisms (Silva, 1995a,b), it is possible that the actual regional species richness and percentage of endemic species are even higher than the ones presented in Table 1. Despite knowledge gaps, the Cerrado is currently considered as the world's most biodiverse tropical savanna.

The ranges of endemic species can cover a small portion or the entire Cerrado. The ranges of the endemic species found across the region define Cerrado as a distinctive biogeographic region. In contrast, the overlap of the ranges of endemic species found only in a small portion of Cerrado define biogeographical sub-regions. Such sub-regions are, in turn, termed areas of endemism. The number of areas of endemism varies according to the taxonomic group, ranging from four among birds (Silva, 1997), to 13 when ranges of amphibians lizards, snakes, and amphisbaenians are combined (Azevedo et al., 2016). The number of areas of endemism within Cerrado is expected to be larger for plants than any vertebrate groups because plants are limited by edaphic factors (i.e., chemical, physical, and biological properties of soils), microclimate, and dispersal modes (Major, 1988). Some areas of endemism are

Table 1 Number of species and percentage of endemic species of Cerrado in eight biological groups.

Biological group	Number of species	% Endemics
Plants ^a	12,097	35.1
Fishes ^b	800	25.0
Amphibians ^c	209	51.7
Lizards ^d	76	42.1
Snakes ^d	158	32.3
Amphisbaenians ^d	33	60.6
Birds ^e	856	3.5
Mammals ^f	251	8.8

common to all biological groups, such as the ones found along the Espinhaço Range, where the top of the plateau is dominated by rocky fields that have a unique set of species found nowhere else (Conceição et al., 2016).

Cerrado endemic species have accumulated over time, indicating a continuous process of biotic assemblage associated with the environmental changes that have been occurring in the region since the Miocene. Among birds, old endemic vertebrate species (i.e., that originated before Pliocene) are restricted to the top of the plateaus whereas evolutionarily young vertebrate species (i.e., originated during the Quaternary) are found mostly on the depressions (Silva, 1997). This pattern seems to be found also among other groups of organisms (Deus Vidal et al., 2019).

Threats and Conservation

The major threat to Cerrado biodiversity is the expansion of commercial agriculture across the region due to the ever-growing global demand for food. Until the 1970s, agriculture in the Cerrado was restricted only to regions with nutrient-rich soils found in the peripheral depressions (Mesquita, 1989). The plateaus, despite their level topography, deep well-drained soils, favorable climate, and a vegetation (cerrado s.l.) that can be easily cleared for farming or cattle ranching, were considered unfit for crop production because of their nutrient-poor, acidic soils. In 1970, only 10.6% of the Cerrado natural vegetation had been cleared (Klink and Moreira, 2002).

Things began to change when the Brazilian Institute for Agricultural Research (EMBRAPA) developed a set of new technologies that helped farmers circumvent the natural obstacles that existed for large-scale commercial agriculture in the Cerrado plateaus (Klink and Moreira, 2002). These technologies include soil fertilization with phosphate and lime; *Rhizobium*-based nitrogen fixation; new crop varieties; heavy use of pesticides and herbicides; “no-till” agriculture (in which crops or pastures are grown from year to year without disturbing the soil through tillage); forest, agriculture and livestock integration (in which fields are used alternately for crops and livestock but windbreak lines of trees are also planted in between the fields, where cattle can forage); and the adoption of modern machinery. In addition to new technology, the Brazilian national government improved road and energy infrastructure and provided very generous government subsidies to farmers (Mesquita, 1989). As a result, large-scale commercial agriculture focused on soybeans, rice, coffee, wheat, maize, sugarcane, and cotton has expanded exponentially in the Brazilian Cerrado with spillovers to Cerrado regions of Bolivia and Paraguay. In 2010, around 53% of the native vegetation of Cerrado in Brazil had been replaced by agriculture fields or other types of land use (Beuchle et al., 2015).

The expansion of agriculture across the Cerrado has caused many environmental transformations that currently threaten the region’s biodiversity. Land use changes have led to habitat fragmentation and isolation, reducing the area available for populations of several species of organisms (Rocha et al., 2018). Soil mechanization of large areas of agriculture exposed bare soil, leading to soil erosion and compaction (Merten and Minella, 2013). Freshwater systems have been affected by pollution caused by the use of fertilizers and pesticides, the establishment of dams for energy production, as well as continuous and unsustainable water withdrawals for irrigation (Nogueira et al., 2010). Finally, although cerrado species and ecosystems are adapted to fire, fire frequency has intensified drastically across the region due to human actions (Durigan and Ratter, 2016).

Cerrado is considered as poorly protected in general, but there are some important differences among countries. In Bolivia, the Noel Kempff National Park (15,230 km²) was gazetted in 1988 with 5412 km² and expanded in 1996 to its current size to protect the country’s largest cerrado area. Because of the park’s remoteness and Bolivia’s comparatively low human population density (especially in the country’s eastern lowlands), the most substantial human threats to this area come from burning associated with ranching operations in neighboring Brazil (Silva and Bates, 2002). In Paraguay, Cerrado is protected in the following public

protected areas: Cerro Corá National Park (55.3 km²), Paso Bravo National Park (1100 km²), Río Negro National Park (1237 km²), Serranía de San Luis National Park (102.8 km²), Cerro Chovoreca Natural Monument (1009 km²), and Cabrera-Timane Natural Monument (1258 km²). In Brazil, there are 418 public protected areas in Cerrado. Altogether these protected areas cover 176,173 km², they represent only 8.6% of the region. The ten largest protected areas with strict protection in the Brazilian Cerrado are: Nascentes do Rio Parnaíba National Park (7498 km²), Serra Geral do Tocantins Ecological Station (7163 km²), Araguaia National Park (5577 km²), Mirador State Park (5000 km²), Chapada dos Veadeiros National Park (2406 km²), Grande Sertão Veredas National Park (2310 km²), Araguaia State Park (2231 km²), Iquê Ecological Station (2159 km²), Serra da Canastra National Park (1978 km²), and Chapada das Mesas National Park (1599 km²).

The lack of balance between use and conservation has increased the extinction risk of many species of animals and plants. According to the most recent estimates there are 1267 threatened species for the Cerrado, of which 979 are plants (Martins et al., 2018) and 288 animals (ICMBIO, 2018).

Changing Climatic Conditions

There is very little doubt that the Cerrado is going to be drastically affected by climate change. For instance, Torres and Marengo (2014) synthesized a large number of climate model projections and found that a large portion of Cerrado can be considered as a persistent climate change hotspot throughout the different forcing scenarios and Global Circulation Model datasets. More specifically, the Brazilian Panel on Climate Change (PBM, 2013) projected that: (1) temperatures will increase by between 1 °C and 5.8 °C in the region, with a drier and warmer period by 2070; (2) flows of all river basins with significant tributaries rivers in the center-west (Tocantins/Araguaia, Paraná, São Francisco, Paraguay and Amazonas) will be reduced for the period 2071–2100, relative to the historical average (1961–90); (3) temperature rises will result in a reduction of the photosynthetic process, which over time can lead to a decrease in plant biomass and a reduction in primary productivity; (4) the increase in the length of the dry period can potentially result in increased vulnerability to fire in the Cerrado, leading to more frequent burning and decreasing precipitation across the region.

The implications of climatic change on the regional ecosystems is still a question open to debate. Studies using techniques of ecological niche modeling indicate that species of plants (de Siqueira and Peterson, 2003; Velazco et al., 2019) and birds (Marini et al., 2009) will lose a substantial portion of their ranges.

The Future of Cerrado

A detailed spatial plan for the prioritization of conservation efforts in the Cerrado has been developed by the Brazilian Ministry of the Environment (<http://areasprioritarias.mma.gov.br/>), and this map recently has been used in developing conservation plans for both plants (Amaral et al., 2017) and vertebrates (Silvano et al., 2016). In addition, the Critical Ecosystem Partnership Fund has developed a detailed ecosystem profile for the Cerrado, to best guide conservation investment in the region (<https://www.cepf.net/sites/default/files/cerrado-ecosystem-profile-summary-english-revised-2017.pdf>). Thus there is an excellent baseline database and scientifically justified planning information for future conservation actions.

However, the Cerrado is home of 25–30 million people who live mostly in large and mid-size cities. These cities, in turn, depends on the natural and agriculture systems that surround them. Climate change threatens both systems and therefore can have a negative impact on the wellbeing of future generations of people living in the region. Hence, Cerrado requires an adaptation plan that is ambitious enough to transform the way by which human development has occurred across the region. Instead, to follow the traditional frontier development model, in which natural resources are perceived as infinite and focus is on short-term gains, societies should pursue a sustainable development model, in which improvements in biodiversity conservation, agriculture production, and social inclusion are enabled by effective governance. The transition to a sustainable Cerrado requires the following urgent actions: (1) conserve all region's natural vegetation remnants; (2) move current agriculture systems to a more sustainable path, by finding ways to increase significantly the productivity while reducing GHG emissions, soil loss, water consumption and pollution; (3) end poverty; and (4) adopt transparent, effective, and participatory decision-making processes across all government levels, from local to national.

Abstract

The Caatinga is a large semi-arid biome located entirely within the northeastern quadrant of Brazil. It is a region with patterns of anomalous precipitation, and with occasional multi-year droughts, which has earned it the label the “Polygon of Drought.” This has affected the adaptations of species within the region as well as the livelihoods of human populations. The major ecosystem types within the Caatinga biome include open canopy thorn scrub woodlands on shallow soils with an abundance of cactus, taller semi-arid forests on sedimentary soils, and tall deciduous and semi-deciduous forests on more nutrient rich substrates. The Caatinga also has a varied topography or small rocky ranges and plateaus. Caatinga biodiversity was once thought to be species poor with low levels of endemism, but recent research has demonstrated a rich flora and fauna with high levels of endemism. The Caatinga, however is highly threatened by poor land use practices and expanding large-scale development, resulting in growing rates of deforestation. This is exacerbated in times of drought, resulting in very low indicators of human development. Although a number of important protected areas currently exist in the Caatinga, they represent a small proportion of the biome and are poorly interconnected.

What is Caatinga?

Caatinga is a natural region that lies in the hinterland of northeastern Brazil (Fig. 1). The term caatinga means “white forest” in Tupi, the language used by the Amerindians that lived in the region (Prado, 2003). Caatinga extends over 900,000 km² and encompasses part of the areas of 10 Brazilian states: Piauí, Ceará, Rio Grande do Norte, Paraíba, Pernambuco, Alagoas, Sergipe, Bahia, and Minas Gerais (Silva et al., 2018a,b). The region is surrounded by the Amazon (on the east), Atlantic forest (on the west), and Cerrado (on the south). In the north, Caatinga reaches the Atlantic Ocean. As is common among biomes everywhere, Caatinga is separated from the adjacent terrestrial biomes by transition zones where types of vegetation with distinct ecological requirements can be found side by side (Eiten, 1972).

Caatinga is one of the most highly distinctive natural regions in South America. Based on the range overlaps of their endemic species, it has been recognized as a dispersal center (Muller, 1973), an area of endemism (Cracraft, 1985; Haffer, 1985), a phytogeographic province (Rizzini, 1976), a phytogeographic domain (Queiroz et al., 2018), and a biogeographical province (Cabrera and Willink, 1980; Udvardy, 1975; Morrone, 2014). Caatinga has also been considered as an ecoregion (Olson et al., 2011), a biome (IBGE, 2004), or a morphoclimatic domain (Ab'Saber, 1973) because it has a unique combination of physical and biological features.

The Landscapes of Caatinga

Caatinga is a heterogeneous region where seasonally dry tropical forest and woodlands (STDFWs), gallery forests, wetlands, tropical rain forests, savannas and rupestrian grasslands compose an intricate mosaic (Queiroz et al., 2018). Caatinga's environmental heterogeneity is, in turn, a consequence of the interaction of geomorphological, soil, and climate factors (Andrade-Lima, 1981). Around 71.4% of Caatinga lies on Precambrian crystalline basement, 23.8% on Paleozoic and Mesozoic sedimentary basins, and 4.7% in Quaternary sedimentary basins. Most of Caatinga (42.3%) is formed by peripheral depressions (0–600 m) that are large flattened or undulating surfaces shaped in both crystalline and sedimentary rocks (Cole, 1986). These depressions are separated by plateaus (600–2200 m) that are locally known as “*serras*,” “*planaltos*,” “*tabuleiros*,” “*chapadas*” or “*brejos*” and that represent residual formations of old erosion cycles (Cole, 1986). Sometimes, intermediate and mid-altitude surfaces locally known as “*patamares*” link the depressions with the plateaus. Regional soils are diverse and several types have been described to the region. The most common soil classes according to the Brazilian Soil Classification System (Santos et al., 2018) are Neosols (18.7%), Latosols (17.1%), Argisols (14.1%), and Luvisols (12.8%). Most Caatinga has a semiarid climate, but there are also patches of semi-humid climate due to orographic effects (Nimer, 1989). The average minimum temperature is 14.8 °C (range = 7.6 °C–28.1 °C), the average mean

Fig. 1 The Caatinga biome is restricted to northeastern Brazil.

temperature is 21.9°C (range = 15.6°C – 28.1°C), and the average maximum temperature is 29.7°C (range = 23.0°C – 36.3°C). The average annual rainfall is 1026 mm a year (range = 346 mm/year–1733 mm/year), but 11% of the region receives less than 500 mm/year and 70% receives less than 1000 mm/year. Rainfall is higher from November to April, but it usually is concentrated in 2 or 3 months within this period (Nimer, 1989). The number of dry months varies from six to eleven, with the length of the dry season declining from the region's center to its edges (Nimer, 1989). Caatinga has a high interannual variability in rainfall (sometimes more than 50%), and droughts, defined usually as those years in which the annual rainfall is less than 30% of the average, can sometimes last for years (Sampaio, 1995). These droughts can have devastating effects on both the ecology of the region and the human population, and the region is referred to as the "Polygon of Drought." Periodic droughts exacerbate the poverty of the region and are part of its history, and a frequent theme in the literature and music of northeastern Brazil.

The dominant vegetation in Caatinga is a SDTFW termed locally as "caatingas" (Andrade-Lima, 1981; Prado, 2003) because it shows a wide variation in structural forms ranging from open cactus scrub (mostly on rock outcrops in the driest areas or areas deeply transformed by human activities; Fig. 2) to tall, semi-deciduous forests on moister sites with nutrient-rich soils

Fig. 2 General appearance of the Caatinga landscape, dominated by cacti, thorn scrub vegetation.

(Andrade-Lima, 1981; Queiroz et al., 2018). From a floristic perspective, there are three subgroups of caatingas: (1) crystalline caatingas, (2) sedimentary caatingas, and (3) caatinga forests. The crystalline caatingas are the most widespread, as they cover 73% of the region (Queiroz et al., 2018). They grow on shallow and very stony soils associated with the crystalline basements that do not retain water for a long time (Fig. 3) and have a flora (Fig. 4) associated with other Neotropical SDTFWs (Queiroz et al., 2018). In contrast, the sedimentary caatingas grow on deep, nutrient-poor sandy soils of the sedimentary depressions and are found as islands in three major patches: The Ibiapaba and Araripé plateaus, the tableland surfaces of the Tucano-Jatobá sedimentary basins, and the sandy dunes of the São Francisco valley (Queiroz et al., 2018). The flora of sedimentary caatingas seems to be more recent and associated with other vegetations on sandy soils in eastern South America (Queiroz et al., 2018). These two groups of caatingas have different phenological patterns, as sedimentary caatingas are not so strongly linked with rainfall patterns, and their floras have different biogeographic connections with other South American biomes (Queiroz et al., 2018). The caatinga forests is the third and most distinctive subgroup among caatingas (Prado, 2003). It can be deciduous or semideciduous and is found on nutrient-rich soils derived from limestone rocks along the valleys of the rivers São Francisco e Gurgéia, on the upland Chapada do Araripe, the Potiguar basin, and along the slopes of the high plateaus of the Chapada da Diamantina (Prado, 2003). These forests are 20–30 m tall and dominated by exuberant trees of the genera *Tabebuia*, *Anadenanthera*, *Myracrodunon*, *Cavanillesia*, and *Schinopsis* (Andrade-Lima, 1981; Prado, 2003). Some studies suggest that this type of vegetation was once more widespread across the region and that it was replaced by open physiognomies and woodlands as a consequence of human disturbances (Coimbra-Filho and Câmara, 1996).

In addition to caatingas, patches of other types of vegetation are found in Caatinga and contribute to increase the regional environmental diversity. For instance, wetlands and seasonally flooded grasslands are found along the main rivers (Siqueira Filho, 2012). Gallery forests with carnauba palm (*Copernicia prunifera*) are found in the riverbeds near the crystalline caatingas (Queiroz et al., 2018). Tropical rain forests with strong floristic connections to Atlantic Forest are found along the slopes of Chapada da Diamantina as well as small and isolated plateaus in the states of Pernambuco, Paraíba, and Ceará (Andrade-Lima, 1982). On the

Fig. 3 Example of the dense thorn scrub understory typical of Caatinga (Photo credit: T. Lacher).

Fig. 4 *Cnidoscolus urens*, a thorny and spiny member of the family Euphorbiaceae. Many Caatinga plants.

top of the Chapada da Diamantina, the Araripe Plateau, and small plateau islands within the region, it is possible to find patches of cerrados, the tropical xeromorphic savanna that dominate the extensive plateaus of Central Brazil, Bolivia, and Paraguay (Eiten, 1972). Rupestrine grasslands are restricted to the most ancient geomorphological surfaces of the Chapada da Diamantina and are a vegetation type rich in species and endemism of plant families with unique adaptations that allow them to thrive in very poor soils (Queiroz et al., 2018).

Caatinga is also a region with unique freshwater ecosystems (Silva et al., 2018a,b). The region has a dense river network composed of both perennial and intermittent rivers. Perennial rivers are few, and their headwaters are generally outside the Caatinga (Steffan, 1977). The São Francisco is the largest and most important perennial river in the region, forming a set of unique aquatic ecosystems along its course. In contrast, intermittent rivers, such as Jaguaribe, are the ones that cease to flow every year or at least twice every 5 years (Steffan, 1977). They can experience flash floods and prolonged droughts, both of which act as agents of hydrologic disturbance and have a strong influence on aquatic biological communities (Silva et al., 2018a,b).

The Biodiversity of Caatinga

In the past, the Caatinga biota was thought to be composed mostly of widely distributed species with few being restricted to the region (Mares et al., 1985). However, recent studies have rejected this hypothesis. In fact, the Caatinga harbors an astounding diversity of native species with a high proportion of endemic species (Table 1), making it one of the world's more diverse and unique tropical drylands (Tabarelli et al., 2018).

In a region with so many endemic species, it is difficult to pinpoint a set of flagship species that can be used as symbols for the region's conservation efforts. Nevertheless, Aguiar et al. (2002) proposed two birds and two mammals as flagship species for Caatinga. The two birds are Lear's macaw (*Anodorhynchus leari*) and Spix's macaw (*Cyanopsitta spixii*), both of which are endemic to Caatinga. Lear's macaw is an impressive metallic blue macaw, superficially similar to the hyacinth macaw (*Anodorhynchus hyacinthinus*), but slightly smaller (75 cm long), with a larger head, and lighter in color. This species is known from two colonies at Toca Velha and Serra Branca, south of Raso da Catarina, Bahia (Collar et al., 2019a). Because of intensive recent conservation efforts, the population of this species has increased from 140 in 1994 to 1123 in 2010 (Collar et al., 2019a). As a consequence, it has been downlisted from Critically Endangered to Endangered in the International Union for Nature Conservation (IUCN) Red List.

In contrast with Lear's macaws, Spix's macaws seems to be extinct in wild (Collar et al., 2019b). This small blue macaw (55–57 cm) with pale greenish blue crown and blackish gray bare facial area once lived in the gallery woodlands dominated by caraíba (*Tabebuia caraiba*) along the river São Francisco valley (Collar et al., 2019b). However, because the destruction of its habitat as well as illegal trapping, its population declined fast. When it was rediscovered in nature, its population had only five individuals. The last known wild individual disappeared in 2000 from near Curacá, Bahia (Sick, 1993). The fate of this species depends on a successful introduction of a few captive individuals in nature.

The two species of mammals that can be proposed as flagship species are the rock cavy (*Kerodon rupestris*) and the Brazilian three-banded armadillo (*Tolypeutes tricinctus*). The rock cavy is a large (700 g) rodent endemic to Caatinga that is distantly related to guinea pigs and that occupies rock outcrops where it lives in crevices and forages on foliage (Lacher, 1981; Lacher et al., 1982). With numerous adaptations to its rocky habitat, the rock cavy has many morphological, ecological, and behavioral similarities to the hyraxes and gundis of Africa (Mares and Lacher, 1987). It also climbs well and often forages high in trees. When disturbed, it gives a rapid, trilling alarm call and flees deep into crevices in the boulder piles. The species is heavily hunted but it is considered as least concern by IUCN Red List (Lacher, 1981).

Different from the rock cavy, the Brazilian three-banded armadillo is considered as vulnerable by the IUCN Red List and its populations are declining because of heavy hunting. It was once thought to be extinct, but Silva and Oren (1993) rediscovered populations in tropical deciduous forest remnants in the state of Bahia. Although it has been observed in the Cerrado (Marinho-Filho et al., 1997; Oliveira 1995), it is largely a Caatinga species. This armadillo has the ability to completely roll itself into a tight ball as a defensive posture (Silva and Oren, 1993). Because of that behavior, it was selected to be the mascot of the 2014 Soccer World Cup. In 2015, scientists demanded that the Brazilian government set aside 1000 ha of protected areas in Caatinga for each goal scored in the tournament (Melo et al., 2014). The Associação Caatinga, an important regional conservation organization, carries on a program to protect the species.

Table 1 Number of species and proportion of endemics in Caatinga for selected biological groups.

Groups	Number of species	% Endemic species	Source
Flowering Plants	3150	23.0	Queiroz et al. (2018)
Fishes	386	54.1	Lima et al. (2018)
Amphibians	98	20.4	Garda et al. (2018)
Reptiles	79	30.8	Mesquita et al. (2018)
Birds	548	23.0	Araujo and da Silva (2018)
Mammals	183	28.0	Carmignotto and Astúa (2018)

The biota of Caatinga has been assembled as a consequence of three biogeographic processes: species production, biotic exchange, and regional mass extinction (Araújo and da Silva, 2018). Species production is the origin of species within the region, biotic exchange is the flow of species between regions, and regional mass extinction occurs when many species disappear within a region as a consequence of regional-scale environmental changes. The relative contribution of each one of these processes seems to vary across biological groups. Because of the high proportion of endemic species within these groups, species production is more important in flowering plants (Queiroz et al., 2018), fishes (Lima et al., 2018), amphibians (Garda et al., 2018), and reptiles (Mesquita et al., 2018). In contrast, because many species living in Caatinga have most of their ranges in adjacent regions, biotic exchange seems to be more prevalent among birds (Araújo and da Silva, 2018) and mammals (Carmignotto and Astúa, 2018). The contribution of the regional mass extinction on the present-day composition of the Caatinga's biota needs still to be investigated, but recent studies indicate that this process could be important at least among mammals (Castro et al., 2014). In the past, it was suggested that species endemic to the Caatinga were evolutionarily young and derived from other regions, such as Atlantic Forest or Chaco (Rizzini, 1976; Andrade-Lima, 1981). However, this hypothesis has been rejected by phylogenetic studies using molecular markers (Queiroz et al., 2018). The estimated ages of the endemic species of the Caatinga range from the early Holocene to Mid-Miocene, indicating that species production has been continuous within the region (Tabarelli et al., 2018). In addition, Caatinga endemic species are related to species that live in different South American regions, indicating a complex network of biogeographic relationships for the region and a very fascinating biogeographic history (Araújo and da Silva, 2018; Queiroz et al., 2018).

As important as an understanding of the biogeographical processes that generated the current Caatinga biota is the identification of the ecological processes that help to maintain the current biodiversity of the Caatinga. Among the several factors suggested in the literature, environmental heterogeneity seems to be the most important. A region with high environmental heterogeneity is expected to maintain more species at local and regional scales than a region with less environmental heterogeneity. The Caatinga is heterogeneous from an environmental perspective. For instance, Rodrigues e Silva et al. (2000) recognized at least 135 geo-environmental units and Velloso et al. (2002) recognized nine ecoregions. Although dominated by caatingas, the presence of enclaves of other vegetation types contributes to sustaining a significantly high number of species across the region. For instance, among birds, almost 60% of the species require forests (a habitat that covers less than 15% of the region) for their life cycles (Araújo and da Silva, 2018). The region's environmental heterogeneity shapes the distribution of the species, forming environmental gradients. These gradients, in turn, are fundamental in providing mesic refuges and migratory corridors during the long dry season for several species that are able to move between habitats within landscapes and between landscapes within the region (Silva et al., 2003). Ecological gradients can also facilitate the speciation among some groups of organisms that have low dispersal, and enable the evolution and the maintenance of complex and unique types of plant-animal interactions (Leal et al., 2018).

Threats and Conservation

Human activities have been documented within the Caatinga since at least the Late Pleistocene and Early Holocene (Bueno and Dias, 2015). When the first Europeans disembarked in Brazil in 1500, the indigenous population in the Caatinga was roughly estimated at 100,000 people (Hemming, 1987). At this time, human impacts on the natural ecosystems of the Caatinga were possibly restricted to the patches of humid ecosystems found along the few perennial rivers and on the plateau slopes, as crops were restricted to a few small plots. During the 1600s and 1700s, European colonizers supported by their African slaves slowly colonized the Caatinga from their coastal settlements. By using the major rivers as routes, they slowly opened up space for settlements that had cattle ranching and subsistence agriculture as their major economic drivers (Hemming, 1987). This expansion of the colonizers led to escalating conflicts with the native peoples, who resented their forcible exclusion from ancient hunting and fishing grounds. The clashes eventually led to the annihilation of the native resistance and the relocation of the few survivors to the harshest zones of the region (Puntoni, 2002). Since then, human settlements have spread out across the whole region and set the basis for the modern cities. In 2010, the Caatinga was home to 28.6 million people, and the region had some of Brazil's lowest human development indicators (Silva et al., 2018a,b). The human footprint can be detected everywhere across the region as traces of pastures, agriculture fields, roads, fire, reservoirs, cities, and other human infrastructure have accumulated over time as a palimpsest (Silva and Barbosa, 2018).

Tabarelli et al. (2018) identified three major types of human disturbances in the Caatinga. The first is acute disturbance caused by the rapid conversion of large areas of native vegetation into human-made ecosystems, dominated by roads, reservoirs, and commercial agriculture (Silva and Barbosa, 2018). The second type is chronic disturbance caused by the slow but continuous overexploitation of the native vegetation, such as through establishing slash-and-burn agriculture, collecting firewood, and browsing by livestock (Albuquerque et al., 2018; Melo, 2018). Finally, the third type consists of the introduction of exotic species of plants and animals (Almeida et al., 2015). These three types of disturbance together are leading to an irreversible loss of biodiversity, biomass, and ecological processes that, over time, reduce the provision of critical ecosystem services (e.g., food, freshwater, and firewood) that local human populations need to survive (Silva et al., 2018a,b). The problem is even larger if one considers that one-third of the Caatinga has a high potential for desertification and that all attempts to control the expansion of the existing four desertification nuclei have not been successful (Sá and Angelotti, 2009; Vieira et al., 2015).

Most of the Caatinga currently is covered by anthropogenic rather than natural ecosystems. Silva and Barbosa (2018) combined the impacts of road expansion, fires, as well as native vegetation loss and estimated that 63.3% of the Caatinga is composed of anthropogenically altered ecosystems. Human impact is higher in the humid and more productive ecoregions than among those

ecoregions where climate and nutrient-poor soils have always constrained human occupation (Velloso et al., 2002). Yet, even the ecoregions that are less amenable to humans have more than 40% of their areas disturbed. In general, the distribution of the natural vegetation across the region shows that most of the remnants are becoming small and isolated and that opportunities to protect large and roadless areas within the Caatinga are quickly becoming scarce (Silva and Barbosa, 2018).

Caatinga is one of the few drylands in the world that has a large-scale science-based conservation plan that was designed together with stakeholders (Silva et al., 2003) and that has been updated by using new datasets and modern decision-making methods (Fonseca et al., 2018). In addition, the region has two large and comprehensive conservation initiatives that have been formally recognized by the Brazilian government: (a) the Caatinga Biosphere Reserve designated in 2001 with 19.9 million hectares and (b) the Caatinga Ecological Corridor announced in 2006 with 11.7 million hectares. However, despite all this effort, the Caatinga continues to be poorly protected (Leal et al., 2003). In fact, only 7.4% of the region is within protected areas and most of these protected areas are not properly funded (Oliveira and Bernard, 2017). If national priorities do not change and more protected areas are not added to the regional system, the future of the Caatinga would inadequately rely on a few large national parks and ecological stations that have areas above 50,000 ha. These protected areas are: the National Park Serra das Confusões (823,435 ha), National Park Boqueirão da Onça (347,557 ha), National Park Chapada Diamantina (152,000 ha), National Park Serra da Capivara (100,000 ha), Ecological Station Raso da Catarina (99,772 ha), National Park Catimbau (622,300 ha), National Park Cavernas do Peruaçu (56,800 ha), and State Park Caminho dos Gerais (56,237 ha).

Changing Climatic Conditions

Because of its current interannual rainfall variability, climate is already a major driver of the Caatinga's socio-ecological systems (Marengo et al., 2016). The situation is projected to get worse because scenarios of future climate suggest that the near surface air temperature will increase between 1 °C and 4 °C and rainfall will reduce by about 0.3 mm day⁻¹ by the end of the 21st century (Torres et al., 2018). In addition, the IPCC (2013) projected with medium to high confidence the following climatic stressors over the Caatinga: (1) surface soils are projected to dry out; (2) both annual evapotranspiration and runoff are projected to decrease; (3) days and nights are projected to be warmer; (4) more frequent intense rainfall episodes will be followed by dry and warm periods without rain; and finally, (5) dry spells are projected to be longer with the possibility of triggering droughts. Climate change associated with desertification make Caatinga one of the world's most vulnerable regions to climate change, with potential adverse impacts on its rich biodiversity, water resources (Andrade et al., 2018), and, consequently, its human population (Torres et al., 2018).

The Future of Caatinga

What is the future of the Caatinga? It is hard to project, however the current indicators are not promising. Despite some progress in the last decades, the region still has very low indicators of human development (Silva et al., 2018a,b). Therefore, social inclusion continues to be a regional issue. From an environmental viewpoint, loss of native ecosystems continues at a fast pace, biodiversity conservation policies are still poorly elaborated, and all efforts to constrain the desertification frontiers have not been successful. Projections about the impact of future climate change on the region are grim and the adaptive capacity available at the regional level to face such changes is limited. A better future for the Caatinga requires the adoption of a development model in which environmental conservation, social inclusion, economic prosperity and good governance go together (Sachs, 2015). A shift toward this model demands visionary leaders, persistence, creativity, innovative science and technology, consistent financial and political support, and a robust and evident connection between the improvement of human livelihoods and the conservation of natural landscapes (Leal et al., 2005). These basic enabling conditions for change have never been in place during the last several decades and, unfortunately, are unlikely to be put in place in the near future.

Abstract

The Dry Chaco is mostly known as a forested ecosystem. However it includes natural grasslands, savannas, scrublands, and wetlands. With one of the highest global deforestation rates in the last two decades and only 12% of the area protected, the concern about land-use change in this ecoregion has raised exponentially; but conservation initiatives developed in last years almost exclusively targeted forests whereas natural grasslands and savannas remain as neglected ecosystem within scientific and governmental agendas. While currently the distribution of natural grassland and savanna area encompasses over 20,000 km², historical records and spatial models indicate that natural grassland and savannas were more widespread in pre-European era. Two main reasons drove this reduction in natural grasslands and savannas: woody encroachment by fire suppression and overgrazing, and conversion to agriculture and implanted pastures. In this article, through a combination of analyzes and bibliographic revisions, we describe biotic and abiotic components of natural grassland and savannas of the Dry Chaco. We also present the current distribution and conservation status of these ecosystems, and describe the process of change and the ecological consequences for biogeochemical cycles and biologic interactions. To provide basis for management, we estimate current grazing stocking rates on natural grasslands and savannas of Argentine Dry Chaco and we propose an alternative approach to sustainably intensify the use of these ecosystems and improve cattle rancher livelihoods. Despite the existent knowledge about natural grasslands and savannas in the region, we believe that is necessary to motivate the scientific community and national institutions to increase efforts to reconcile the restoration and conservation of these particular rangelands.

Introduction

The Dry Chaco is, for the most part, a vast sedimentary plain, essentially modeled by the action of rivers that cross it in a northwest-southeast direction. Expanding from 33.8 to 22°S and from 67.5 to 59.2°W, this ecoregion is mostly known for its forests. However,

it includes natural grasslands, savannas, scrublands, and wetlands (Adamoli et al., 1990; Navarro et al., 2006). With one of the highest global deforestation rates in the last two decades (Baumann et al., 2016; Grau et al., 2005), and only 12% of the area protected, the concern about land-use change has raised exponentially, and some governmental initiatives for conservation have been taken, such as the promotion of a national forest conservation law in Argentina. However, agriculture does not only expand into forests but also into natural grasslands and savannas with less energy to plow up and convert them, representing a major conservation challenge for the scientific and governmental agendas (Grau et al., 2014).

Albeit the introduction of European livestock into South America started in the 16th century (Bishko, 1952; Kunst et al., 2003), it was not until the beginning of the 20th century that cattle ranching began to spread into the Chaco rangelands (Adamoli et al., 1990). By 1930, the excessive stocking rate had degraded the herbaceous forage resources, and started its own decay (Morello and Saravia Toledo, 1959). As with other semi-arid regions of the world (Smith, 1899; Griffiths, 1904; Wooton, 1908), such overabundant cattle for many years favored scrubland expansion while herbaceous cover and productivity decreased in natural grasslands and savannas.

Domestic livestock-driven degradation of semiarid rangelands remains controversial in climates with high annual rainfall variability (von Wehrden et al., 2012) as some areas of the Dry Chaco. But, a sum of evidence, including historic registers, town names, and distributions models, indicates that the extension of natural grasslands and savannas was much larger prior to domestic livestock expansion in the early 20th century (Grau et al., 2014; Kunst et al., 2003). The degradation process of natural grasslands could have been reinforced by the sedentary character of the main cattle grazing production system in that period: the “puestos,” in which cattle is managed centered around a water source (commonly near the center of ranch) shaping a 70–150 km² “piospheres,” and without transhumance in periods of fodder shortage (Adamoli et al., 1990) contributing to the overgrazing process.

There are still many information gaps at different scales in natural grasslands and savannas of the Dry Chaco. For example, we do not know the pre-European distribution of these natural rangelands, since such knowledge would require detailed paleo-ecological research inexistent to date. Neither the current state of degradation, nor even knowledge of the physiognomy and distribution of the “old-growth” grasslands (see Veldman et al., 2015), which could represent the most valuable information in terms of conservation, is known. The role of these ecosystems in biological interactions, biogeochemical cycles and the provision of ecosystem services has been superficially explored to date. The sum of these information gaps represents the first obstacle to determine conservation areas and apply restoration practices in these natural areas with the least impacts on the well-being of local communities.

Currently Dry Chaco presents multiple challenges, with large undeveloped reserves of natural resources (principally native forest), widespread poverty, extensive livestock supporting the subsistence of thousands of small farmers, and one of the most active agricultural frontiers with the associated conflicts for land tenure, nature conservation, and regional development. This chapter revises the existent knowledge about natural grasslands and savannas in the region, as a way to motivate the scientific community to increase efforts in understand these ecosystems to reconcile the restoration, conservation and sustainable development. Although we aim at addressing the entire ecoregion in this article, the discussed analyses mostly involve the Argentine Dry Chaco (which encompasses 69% of the region), due to the paucity of information for the Bolivian and Paraguayan areas.

Specifically, in this article we (1) describe the current distribution and typologies of grasslands of the Dry Chaco; (2) discuss the recent and historical drivers that resulted in present-day patterns; (3) describe the soils, climate, and floristic composition of natural savannas; (4) discuss the current drivers of natural grassland transformations, their management, and their impact in ecosystem services; (5) estimate the cattle stock grazing for the Argentinean part of the region to explore opportunities for sustainable intensification to conserve these ecosystems; and (6) describe the role of native grasslands for biodiversity conservation in relation to the current conservation status of the region.

Natural Grassland and Savannas Typologies and Distribution

Using Landsat TM and ETM+ image composites and identifying different spectral signatures (Baumann et al., 2016) we mapped natural grasslands in the entire Dry Chaco (i.e., including Argentina, Bolivia and Paraguay) (Fig. 1). However, it was not possible to discriminate among the different types mentioned below, as well as to discriminate old-growth natural grassland and savannas (Veldman et al., 2015) from grasslands generated in post agriculture early successional stages of vegetation. Based on this analysis, we estimate that natural grasslands area extends over 20,369 km² (Table 1).

The majority of natural grasslands and savannas are located in the southeast limit of the region, towards drier and colder conditions in Cordoba, and southern Santiago del Estero provinces, representing near 60% of the total. In Bolivia and Paraguay, grasslands are more scattered than in Argentina. In the west of Santa Cruz (Bolivia) exist a concentration of edaphic natural grasslands associated with sandy soils representing near 10% of the total area of the region.

We briefly describe four main types of grasslands and savannas of the Dry Chaco region and mapped the distribution of natural grassland and savannas for the entire area (Fig. 1). More detailed descriptions of vegetation physiognomies can be found for Bolivian Chaco (Navarro and Fuentes, 1999), Paraguayan Chaco (Navarro et al., 2006), and for the Argentinean Dry Chaco region (Morello et al., 2013). Based on these, we identify the following typologies:

1. Grassland and savannas located in lowlands close to rivers and permanent waters bodies; typically with poorly drained clay, high water table and recurrent flooding, often with high salt content. These grasslands and savannas are mainly concentrated in the Dulce river basin or wetlands as Bañado del Izozog or Bañado de la Estrella. These areas are not suitable for agriculture and are

Fig. 1 Current distribution of natural grasslands and savannas in the Dry Chaco region (Argentina, Bolivia and Paraguay). In gray, the ecoregion of Humid Chaco.

Table 1 Estimated extension of natural grasslands by first order national subdivision for 2013.

Country	First order national subdivision	Natural grassland area (km ²)	Relative extension (%)
Argentina 16,595 km ² (81.5%)	Córdoba	7040	34.6
	Santiago del Estero	3945	19.4
	Chaco	1228	6.0
	Salta	1134	5.6
	San Luis	1049	5.1
	Formosa	829	4.1
	Catamarca	511	2.5
	Tucuman	367	1.8
	Santa Fe	337	1.6
	Jujuy	78	0.4
	La Rioja	74	0.4
	San Juan	2	0.0
Bolivia 2548 km ² (12.5%)	Santa Cruz	2033	10
	Chuquisaca	261	1.2
	Tarija	253	1.2
Paraguay 1226 km ² (6%)	Boquerón	862	4.2
	Alto Paraguay	182	0.9
	Presidente Hayes	182	0.9
Total		20,368	

mainly used by extensive traditional grazing livestock. In the area comprising northern Argentina and southwestern Paraguay and southern Bolivia, they include palm savannas dominated by *Trithrinax schizophylla* and *Copernicia alba* as tree components (Fig. 2).

2. Edaphic grassland and savannas. They are situated in low fertility sandy soils associated with ancient river meanders ("paleo-cauces"). They are found in the northwest of the Bolivian Chaco; and Argentina (center of Santiago del Estero province) and the

Fig. 2 Poor drained and regular flooded Savanna with a *Copernicia* palm woody component (Formosa province, Argentina). Photo by courtesy of Alejandro Brown.

area of influence of the Juramento, Bermejo and Pilcomayo rivers (Salta and Formosa provinces). They are also used mostly for low-intensity grazing. Recurrent fires maintain the herbaceous cover of grasslands dominated by *Elionurus muticus*, with isolated trees of the genera *Prosopis* ("Algarrobos") and *Aspidosperma* ("Quebrachos blancos").

3. Mesic grasslands and savannas. Commonly located in deep and fertile soils. They are concentrated in the east of Santiago del Estero province and west of Chaco provinces, Argentina. To persist, they need recurrent fires generating in a positive feedback associated with high flammability and post-fire resprouting capacity of the dominant grasses. Given their high agriculture potential, most of them have been converted into croplands and implanted pastures.
4. Montane grasslands located in the south and western borders of the ecoregion (Cordoba and San Luis province in Argentina; Sierra San Miguel in Bolivia). Commonly dominated by *Festuca hieronymi*, they can alternate with short grasslands in shallow rocky soils patches. These grasslands are used in extensive cattle ranching, as topography limits croplands in these fertile soils. In the Cordoba provinces they have also been replaced for pine plantations in extensive areas.

Historic Land-Use Changes Affected Dry Chaco Grassland Present Day Distribution

In 1950, the geographer Carl Sauer claimed that all the world's grasslands had coevolved with humans and fire for some 200,000 years (Sayre et al., 2017). In South America, before the expansion of European land uses, descriptions indicate regular use of fire by indigenous communities to hunt and to preserve open areas (Jolis, 1972).

The Chaco was not the exception, and indigenous uses likely persisted for most the 19th century, since the region was mostly outside the colonial influence (Métraux, 1946). However, with the introduction of cattle following the colonization by "Criollos" people in Argentina and Mennonites in Paraguay and Bolivia, a process of overgrazing and depletion of fine fuel in grasslands changed fire regimes and reduced herbaceous cover, and shrub encroachment spread over natural grasslands and savannas. Such processes took place mostly from 1890 to 1950, according to different authors (de Maurice et al., 1919; Muello, 1926; Morello and Saravia Toledo, 1959). The restoration of herbaceous productivity began to be done through the implantation of exotic and more productive pastures. For example, in the early 1950s, Robert Unruh, an agronomy engineer, introduced the first exotic grass (*Pennisetum ciliaris*) in the Paraguayan Dry Chaco, starting the expansion of implanted pastures in the region (Glatzle, 1999). In Bolivia, the British Mission in Tropical Agriculture started the shift from natural grasslands to implanted pastures, introducing many of the most successful cultivated pastures in the 1970s (Killeen et al., 2008). In the montane grasslands of Cordoba natural grasslands have been used for cattle ranching for at least 400 years (Díaz et al., 1994), with well-documented processes of overgrazing and soil erosion (Menghi et al., 1978).

The historical importance of natural grasslands and savannas in the Dry Chaco has been analyzed particularly for northern Argentina by Grau et al. (2014), combining approaches as historical assessments, environmental modeling, and toponyms that refer to natural grassland. Such analyses consistently shows that, in the past, many sectors of the northern Argentine Dry Chaco (mainly towards the limit between Formosa and Salta provinces and the east sector, covering areas of Chaco, Formosa and Santiago del Estero provinces) likely included extensive areas of natural grasslands and savannas as part of the pre European landscape.

Environmental Characteristics

Climate and Soils

In the Dry Chaco, the presence of pronounced climatic gradients together with heterogeneous geomorphological characteristics, generate a diversity of environments reflected in vegetation physiognomies (dry and flooded savannas, estuaries, marshes, salters, and a great extension and diversity of forests and shrublands) (Adamoli et al., 1990). Despite such heterogeneity, the Dry Chaco plains host one of the largest global reserves of fertile soils that are still uncultivated (Lambin et al., 2013), which in combination with flat terrain and low population density facilitates the expansion of large-scale mechanized agriculture.

In Koppen's classification for South America (Peel et al. 2007), the Dry Chaco region is included within three climatic regions: subtropical humid, warm semiarid, and cold semiarid. Subtropical humid host the South American "heat pole," defined as the territory where absolute maximums exceed 47 °C (e.g., Rivadavia district in Argentina or 44 °C in Filadelfia department in Paraguay). In the southern portion of the region, mean annual temperatures range from 23 °C to 18 °C (in La Rioja and San Luis), with absolute minimum temperatures as low as −10 °C/−15 °C (GTZ, 2006 Atlas Gran Chaco). Inter-annual rainfall is highly variable and occurs mainly during the warmer months, and about 80% is concentrated between October and March (Capitanelli, 1979). However, in years during the "El niño" phase of the climatic southern oscillation, autumns and winters tend to be rainy (Glatzle, 1999). Rainfall ranges from 800 mm to 200–300 mm per year. The wettest areas are located in eastern sector, close to the Humid Chaco, and in the western sector in transition with the Yungas ecoregion; and driest areas are located towards the south, in San Luis and La Rioja provinces (Boletta, 1988).

All the permanent fluvial systems, such as Pilcomayo, Bermejo, Juramento-Salado and Salí-Dulce, are allochthonous; i.e., they do not receive affluent in their journey through the ecoregion (Burkart et al., 1999). There are at least two important intermittent rivers for the subfluvial flows, the Del Valle and the Dorado. With the exception of these rivers, permanent water bodies are strange in the Dry Chaco, constituting the principal limitation to rural population and livestock (Glatzle, 1999). The shallow subterranean water is commonly briny, for which rainwater harvesting constitutes a key technology in the region (Magliano et al., 2015).

The Dry Chaco region lies in a structural environment of sedimentary basin, and as a unit of relief it transcends regional boundaries and extends between the crystalline massif of Brasilia, and the Andes mountain range. The behavior of the sedimentary basin is governed by a tendency to sink, at very slow speeds, but continued from the Paleozoic until today which has led it to remain depressed with respect to its peripheral areas, and to receive as sediments the eroded materials of those. With exceptions of mountains in the south and northwestern borders (including mountain ranges up to 2000 m.a.s.l.), topography is mostly flat, and elevation rarely exceeds 200 m.a.s.l., in a gentle regional slope from northwest to southeast (Moretti et al., 2018). In the region there is a diversity of parental materials due to different areas of contribution and sedimentary processes, which determined the composition and particle size in soils. However, the dominant materials are fluvial sediments, and to a lesser extent area, lacustrine and eolian (Moretti et al., 2018).

The dominant order soils are Mollisols and Alfisols; and to a lesser extent, Entisol, Inceptisol and Aridisol (Moretti et al., 2018; SAGYP-INTA, 1990). A huge proportion of soils has moderate to well-developed profiles. Mollisols are mostly developed from loess sediments. They have thick surface A horizons rich in organic matter, and show varying degrees of development in accordance with drainage conditions and their moisture regimen: the presence of an argillic subsurface horizons (Bt) (Argiustoll or Argiudoll) in the humid areas, but in slightly drier areas dominate Haplustoll (A- AC-C or incipient Bw). In this situation accumulations of calcium carbonates in depth are common (Ck). The Alfisols are present in the plains, and they were developed from fine-textured materials, generally associated with the original forest and shrub vegetation. They are deep soils with thick clayey Bt horizons. In general, the soils of the region have high percentages of base saturation, neutral to basic pH and medium values of CEC, and the mottles and gley features are common.

Floristic Composition and Diversity

In poorly drained and regularly flooded grassland and savannas, the woody stratum is commonly dominated by the presences of *Prosopis ruscifolia*, finding also species such as *Bulnesia bonariensis* or *Bulnesia sarmientoi*, *Capparis retusa* or *Capparis tweddiana* and *Acacia cavens* or *Acacia monacantha*, *Loncocharpus fluvialis*, *Tabebuia nodosa*, *Parkinsonia aculeata* and palms such as *Trithrinax schizophylla* or *Copernicia alba* (Fig. 2). The herbaceous stratum is dominated by the grasses *Cenchrus pilcomayensis*, *Schizachyrium condensatus*, *Sporobolus phleoides* and *Heteropogon contortus*; and other common herbaceous species of the genus *Eupatorium* (Asteraceae) and *Solanum* (Solanaceae). Halophytic vegetation appears in soils with high level of salt, such as the floodplain of the lower Dulce river, and it is mainly represented by *Allenrolfea vaginata*, *Atriplex* spp., *Stetsonia coryne*, *Prosopis ruscifolia*, *Maytenus vitis-idea*, and *Spartina argentinensis*.

In edaphic natural grassland and savannas (Fig. 3), grasses are dominated by *Elionorus muticus* (syn. *Aibe*, *Espartillo* or *Paja amarga*), which can reach 30–90% of grass cover. These species are very flammable, with terpenes in foliage that reach maximum concentration in spring, in coincidence with environmental conditions predisposing to fires in the region (Bravo et al., 2001a; Hess et al., 2007). Bucher (1982) defined these landscapes as pyrogenic savannas. *Pennisetum frutescens*, *Heteropogon contortus*, *Pappophorum pappiferum*, *Digitaria californica*, *Schizachyrium tenerum*, *Trichloris pluriflora*, *Bothriochloa laguroides* are other grass species of pyrogenic savannas, and the later three have high tolerance to fires due to survival of underground parts and high re-sprouting capacity. Some herbaceous *Fabaceae* species, such as *Rynchosia senna* and *Indigofera parodiana*, enhance grassland forage potential due to nitrogen content. *Asteraceae* species, such as *Bacharis pingraea* and *Baccharis trimera* are common in *E. muticus* savannas; and fires

Fig. 3 Edaphic savanna in lowlands of Dry Chaco (Northwest of Santiago del Estero, Argentina). Photo by courtesy of Sandra Bravo.

can promote the recruitment of rare species, such as *Dimerostemma hieronymi*. Rhizomatous and perennial species vegetate successfully in these disturbed environments, reestablishing through underground organs. *Lippia turbinata*, *Aloysia gratissima*, and *Lantana* sp. are *Verbenaceae* species containing aromatic components that can feedback fire recurrence, increasing grassland flammability. Isolated trees of *Aspidosperma quebracho-blanco*, *Prosopis nigra*, *Prosopis kuntzei* and small shrubby patches of *Vachellia aroma*, *Schinus bumeloides*, *Schinus fasciculatus* and *Celtis ehrenbergiana* are scattered across these savannas. In Bolivia appear *Schinopsis cornuta* trees.

In mesic grassland with deep and fertile soils (Fig. 4), herbaceous strata are dominated by the Poaceae species *Trichloris crinita*, *Trichloris pluriflora*, *Gouinia paraguariensis*, *Gouinia latifolia*, *Setaria argentina*, *Setaria gracilis*, *Digitaria sanguinalis*, *Pappophorum pappiferum*, *Pappophorum mucronulatum* (Herrera et al., 2003). *Acacia caven*, *Senegalia gilliesii*, *Larrea divaricata*, *Celtis ehrenbergiana* and *Condalia microphylla* are the most common woody invaders in these grasslands (Cabido et al., 2018).

In the montane environments, pure grasslands are rare and dominated by C4 species below 1000 m.a.s.l. Above this elevation ground cover dominance turns towards C3 species up to close to 2000 m.a.s.l. (Cabido et al., 1997, 1998) and grasslands become a common physiognomy. As altitude increases and temperature decreases, grasses of the genera *Nassella* and *Festuca* take over the landscape from 1000 to 1850 m.a.s.l. The most common physiognomy is *Festuca hieronymi* tussock communities that alternate with short grasslands and grazing lawns (Fig. 5). Short grasslands are found in shallow, rocky and dry soil patches. Grasses *Nassella* spp., *Aristida spagazzinii*, *Schizachyrium spicatum*, *Eustachys retusa* and forbs *Dichondra sericea*, *Margyricarpus pinnatus*, *Acalypha communis*, *Baccharis* spp., *Galactia glaucophylla*, *Lucilia acutifolia* are common. Grazing lawns are found in terrain concavities with poor drainage. These are the flattest areas in the landscape and are crossed by permanent or temporal water courses, both factors that improves habitat condition for cattle, increasing grazing pressure. *Paspalum notatum*, *P. dilatatum*, *Steinchis mahians*, *Sporobolus indicus*, *Axonopus fissifolius*, *Cyperus* spp., *Bulbostylis* spp. and *Trifolium repens* thrive here. Short grasslands and lawns are found in the extremes of both soil depth and soil moisture gradients, in between the landscape is dominated by *Festuca hieronymi* tussocks, accompanied by climbing or shade tolerant species such as *Cologania broussonetii*, *Tragia geraniifolia*, *Oxalis conorrhiza*, *Chevreulia sarmentosa*, *Pfaffia gnaphalioides*, *Eryngium horridum* and *Dichondra microcalyx* among others.

Ecosystem Management and Properties

Rangelands provide multiple ecosystem services, but only few of them have market value (Sala and Paruelo, 1997). Further, the demands and perceptions on these ecosystem services vary among stakeholders (Lamarque et al., 2011), and geographical regions (Anadon et al., 2014). In the case of the Chaco's ranchers, the use of herbaceous biomass as fodder constitutes the main demand.

When agriculture is possible, as in the mesic and mountain natural grasslands, the major threat to such ecosystems has been an accelerated conversion to crops in mesic grasslands or to pine plantations in mountain grasslands. However, most natural grassland and savannas of the Dry Chaco have undergone two major transformation processes: the degradation by overgrazing and the increasing of productivity with exotic grasses. Both processes probably have been propelled by the demand for herbaceous forage and resulted in changes in ecosystem structure and function. Below, we discuss the patterns emerging from the local literature, and contrast them with global patterns described in international rangeland literature. In addition, we highlight regional information gaps and outline an avenue to restoration of these singular ecosystems.

In natural grasslands and savannas of the Dry Chaco, differences in vegetation structure and functionality are driven by hierarchically organized factors, including climate, topography, soil development and textures. However, these differences are blurred by past vegetation management, principally carrying capacity and disturbances regimes (Kunst et al., 2006).

Fig. 6 Cattle, puestos and herbaceous biomass dynamic during the 20th century. Adapted from Adamoli, J., Sennhauser, E., Acero, J.M., Rescia A., 1990. Stress and disturbance: Vegetation dynamics in the Dry Chaco region of Argentina. *Journal of Biogeography* 17, 147–156.

Mismanagement of carrying capacity often leads to an increase in woody species (Fig. 6) (Adamoli et al., 1990; Bucher and Huszar, 1999; Kunst et al., 2006). Woody encroachment has been described as a global phenomenon (Sala and Maestre, 2014), occurring at similar rates across different continents (0.1–1.1% of cover/year) (Barger et al., 2011; Stevens et al., 2017), but faster in rangelands with high rainfall variability, as in the case of the Chaco, as the resulting lower predictability makes optimization of the carrying capacity more difficult (Kiage, 2013). Sedentary pastoralism (as opposed to transhumance strategies) has been mentioned as a sociological driver of rangeland degradation worldwide (Sayre et al., 2017). In the Dry Chaco rangelands, particularly in areas with limited bodies of water, sedentary pastoralism has been a predominant system across different scales of cattle ranching systems: smallholders in puestos, with the establishment of a ranch near a water body; and large scale producers with fences and different grazing managements. In addition, an increase of fire frequency from the 1970s and the resulting nitrogen volatilization (Archer and Predick, 2014) and increased atmospheric CO₂ might also be drivers of the increase of woody cover (Grau et al., 2014).

With the aim of restoring herbaceous productivity, active woody encroachment controls such as prescribed fire and mechanical controls have been used in the region (Blanco et al., 2005; Kunst et al., 2012; Ledesma et al., 2018). These practices commonly include the seeding of exotic C4 grasses: *Megathyrsus maximum* in the wettest areas, *Pennisetum ciliare* in the driest areas (Houspannosian et al., 2016), or *Chloris gayana* in halomorphic soils. Despite their similar physiological pathway (i.e., C4, as with many native grasses), exotic grasses often become dominants in basal cover, multiplying up to four times grassland productivity (Blanco et al., 2005; Kunst et al., 2012), but reducing biodiversity in the herbaceous community. This increase of productivity by a monodominant species implies a stronger phenological seasonality than multispecies natural grasslands leading to changes in ecosystem functionality and in some cases constituting “novel” ecosystems (Hobbs et al., 2009).

The consequences of the mentioned replacement for biogeochemical cycles and biological interactions are understudied but potentially important aspects that should be addressed. For example, Macchi et al. (2013) found characteristic bird assemblages in natural grasslands that differed from that found in *Megathyrsus* pastures. However, the interaction of wild primary consumers (i.e., mammals and insects) needs to be much better understood. While carbon losses in soil storage by woody encroachment in natural grasslands and savannas are a process documented at global scale for rangelands (Eldridge et al., 2011), is a poorly understood process in the Chaco.

Ecosystem degradation or restoration are context specific and non-linear processes in rangelands, making difficult general management decisions. In contrast, adaptive management practices to restoring herbaceous productivity while maintaining a broad set of ecosystem services should be carried out contemplating differences in ecological sites, production systems and socioeconomic characteristics across different grasslands typologies of Dry Chaco.

State and transitions models plus the definition of ecological sites has been adopted in the northwest of Santiago del Estero province in Chaco region (Kunst et al., 2006) and should be considered as a promising framework for tackling rehabilitation of natural grasslands and savannas with less impacts in biodiversity while still maintaining social and economic values (Fig. 7). To make a regional assessment of the states of the grassland and savannas of the region, the map generated in this article (Fig. 1), in combination with soil maps and vegetation surveys and field validations, could be helpful in the evaluation of the state of degradation in different ecological sites of the region (Bestelmeyer et al., 2009). The next step should be to elucidate the management practices or the intrinsic conditions that drive the changes of states with respect to the references sites across the diversity of natural grassland and savanna types. Finally, it is necessary to monitor effects of restoration and management practices (including fire and mechanical woody control, and different stocking rates) on biodiversity and productivity. Participatory approaches among stakeholders could make a more effective and integrated assessing and monitoring regime for a large region such as the Dry Chaco, as occur in other regions as in United States rangelands where this approach is improving the capacity to make regional assessments (Bestelmeyer et al., 2017).

Conservation and restoration initiatives should also match with economic incentives for ranchers. Alternatives include subsidies for meat or milk produced in these natural grasslands and savannas, tax reductions, certification schemes to facilitate ecosystem stewardship to conserve multiple ecosystem services while they are still being economically productive. The increase in the awareness of the variety of ecosystem services provided by these rangelands would help for the conservation of these ecosystems. For example, the partial replacement of montane grasslands by pine plantations in Córdoba province has been affecting the magnitude and temporal distribution of stream and river flows, with the water yield in afforested watersheds being 48% less than in

Fig. 7 The common transitions of natural grasslands in Dry Chaco and their relation with biodiversity and social economic value. In dotted lines is the unusual transition of rehabilitation.

grassland watersheds (Jobbágy et al., 2013). In the end, the principles of rangeland management would be more appropriately portrayed as those of the science of managing trade-offs among ecosystem services, and negotiating among stakeholders with competing interests. Thus, as Dry Chaco natural grasslands and savannas will become more valued as singular ecosystems and suppliers of broad ecosystems services for the society, interest on its research and conservation will increase (Fig. 7).

Fire Regime

Fire is one of the main disturbances in Dry Chaco grasslands and savannas. The fire regime (i.e., extent, frequency, severity and intensity) defines the role that fire plays in the ecosystem, affecting soil and plants. The fire season in Chaco region coincides with the prolonged dry season between April and October. Studies about historical fire regimes in grasslands and savannas of the region are scarce, due to the absence of fire records. However, paleo-environmental evidences suggest the natural occurrence of fire events at least over the last 4500 years, with fluctuations in their frequency and intensity related to climatic changes (Di Lello and Linscoug, 2018; Linscoug, 2016).

Under current environmental conditions, grasslands and savannas dominated by natural grass can produce 1000–6000 kg DM ha⁻¹, depending on growing season rainfall. These loads of fine fuels can generate medium to high intensity fire events, with flame height reaching three meters (Kunst and Bravo, 2003). The positive association between fine fuel availability, fuel desiccation, and fire severity was confirmed in manipulative studies using experimental burns and controlled fine fuel loads in Chaco environments (Bravo et al., 2014; Ledesma et al., 2018). Higher fine fuel loads, low moisture content, and higher temperatures during the end of the fire season generate more severe fires. Most fires are concentrated in open areas managed for livestock, where fires are intentionally set with the aims of promoting palatable grass regrowth and woody encroachment control. The ecosystem stresses of overgrazing, excessive use of fires (and a consequent nitrogen volatilization), and droughts facilitate woody encroachment with significant losses in biodiversity and forage productivity both for wild and domestic herbivores.

Historical dendroecology descriptions of fire regimes indicate that water availability in the previous growing season, and subsequent fuel desiccation, controlled fire frequency and extension and resulted in a mean fire interval (MFI) of 3.3 years over the 1925–2000 period with a significant increase in fire frequency from the 1970 decade, attributed to greater water availability at the regional level (Bravo et al., 2010). Before 1970, mean annual precipitation was 496 mm and MFI was 5.63 years. An increase in ~100 mm above such mean annual precipitation reduced MFI to 2 years, and more extensive fires occurred. Other dendroecological studies using fire scar height as an indicator of fire severity indicate that fires were more severe after 1970, and fires scars in trees were identified up to 4.30 m heights (Bravo et al., 2001a,b). These historic data suggest a high frequency fire regime of medium to high severity occurring in the last several decades in the Dry Chaco.

Fires usually increase herbaceous species diversity in natural grasslands and savannas during the 3–4 years after fire, when natural grasslands and savannas gradually recover their initial biodiversity (Kunst et al., 2003). The date of fire occurrence can modify its effect on herbaceous biodiversity, due to pre and post fire environmental conditions and species phenological status.

Experimental burns at the mid-fire season (June to July) generated higher diversity than during early (April to May) or late (October) fires, probably due to better post fire environmental conditions close to spring. Late experimental burns are usually of high severity; thus, prescribed burns at the mid-fire season could be desirable to restore herbaceous species diversity in Chaco natural grasslands and savannas.

Isolated trees of *Aspidosperma quebracho-blanco*, *Prosopis nigra*, *Prosopis kuntzei*, or small shrubby patches of *Vachellia aroma*, *Schinus bumeloides* and *Celtis ehrenbergiana* are scattered across these savannas. The effects of fires on the tree components of Chaco savannas depend on species adaptations and regeneration strategies. Traits such as bark thickness, bud bank size, and reproductive mature age determine woody species maintenance in savannas. For example, *A. quebracho-blanco* is one of the most fire-resistant tree species in Chaco savannas, due to its thick bark (Bravo et al., 2008). Fabaceae species such as *Prosopis nigra*, *P. kuntzei*, *Vachellia aroma*, and *Schinus* sp., among others, have an important aerial bud bank, which allows these species to resprout from aerial organs after low-intensity fire events. Certain species also exhibit buds in underground organs, and can thus reestablish after high-intensity fires through basal resprouts (Bravo et al., 2014; Ledesma et al., 2018). The maintenance of tree habits in these species depends on bark thickness increase rate, and on the fire intervals in natural grasslands or savannas (Bravo et al., 2018).

Assessing the Role of Natural Grasslands in Cattle Grazing, and Exploring Sustainable Intensification Opportunities

Assessing cattle stock rates that can graze in natural grassland and savannas is an initial step to design restoration processes on natural grasslands and savannas with lower impacts on ranchers' livelihoods. At a regional scale, natural grasslands and savannas do not seem to be crucial for cattle diet, since their currently extension is $\sim 20,000 \text{ km}^2$ (less than 0.5% of the region). With an average productivity of $3500 \text{ kg ha}^{-1} \text{ year}^{-1}$ of DM, the total share of natural grasslands could be enough to feed 2 millions of animal unit equivalents ($3600 \text{ kg of DM year}^{-1} \cdot \text{a.u.}^{-1}$, this is an average of c. 1 cattle per hectare). This amount could be enough to satisfy the requirements of 15% of the total stock of the entire Dry Chaco (around 12 million of cattle heads for Argentina, Paraguay and Bolivia). However, this rough number does not reflect diversity in herbaceous productivity or cattle management, and analyses at farm level could be key to understanding the role of these ecosystems in ranchers' livelihoods. In this section, we explore for the Argentinean Dry Chaco, the stocking rate of natural grasslands and savannas and simulate different scenarios of beef production exploring the possibility of sustainable intensification of cattle ranching.

Cattle Grazing in Natural Grasslands and Savannas

We estimate how much cattle can graze in natural grasslands and savannas, exploring the cattle density in these ecosystems for the Argentinean Dry Chaco (80% of Dry Chaco natural grassland and savannas), where we have more detailed information. This rough estimate does not reflect the real current use by ranchers, the state of degradations, nor the role of natural grasslands in relation to other components of the productive system. To refine the analysis we selected $1 \times 1 \text{ km}$ grid cells of the above-presented map (Fig. 1), with more than 50% of natural grassland share; and considered them as centers of a 3-km radius buffer for which we computed cattle stock using explicit geospatial cattle distribution data provided by foot and mouth disease vaccination of the Servicio Nacional de Sanidad y Calidad Alimentaria (SENASA) for 2017. Combining these data, we summed the potential maximum number of cattle heads that could be using natural grasslands and savannas as a forage source. Our results showed that near 720,000 cattle heads occur at less than 3-km of radius for the total extension of $16,000 \text{ km}^2$ of natural grassland and savannas in the Argentinean Dry Chaco (Fig. 8). This stock represents 13% of the total stock for Argentine Dry Chaco.

Assessing Potential for Cattle Intensification

We also explored the possibilities for sustainable intensification (e.g., Garnett et al., 2013; Thomson et al., 2019) for cattle ranching. To do so, we performed dynamic simulations on 42 theoretical farms of cow-calf systems (i.e., productions systems oriented to production of calf to later finishing) across an extension of 14 millions of hectares with different landscape composition, soil (i.e., dominant texture) and climate, using a calibrated and evaluated biophysical cattle management model developed by Nasca et al. (2015). For each of these theoretical farms, we evaluated the following four scenarios in a gradient of intensity: M0 (baseline) cattle ranching developed on natural grasslands fodder sources with conventional management and low technological level; M1, which applies changes in cattle management (adjust of carrying capacity with climate variations, management of service in cows, strategic supplementation for rearing heifers, etc.), on the same landscape and fodder sources as M0; M2, which incorporate implanted pastures as fodder source, and includes same management as M1; and M3, equal to M2, but incorporating corn silage in cows diet. The interannual variability of carrying capacity of M0 was taken as the maximum acceptable threshold to select the outputs of M1, M2 and M3. For these, we carried out five simulations for each scenario modeled, selecting the one that fulfilled the highest productivity and less variability than M0. This condition was fundamental to evaluate resilient stocking rates through climatic variations.

In general, the results showed an increase in beef production (that range from 80% to 2000%) in all scenarios in relation to the baseline (M0), indicating broad opportunities to increase beef production in Dry Chaco (Fig. 9). This increase varied across different edaphic-climatic conditions, showing the environmental constrain for beef production improvements. For example, the drops in beef production in M3 are explained by a dominance of sandy soils and consequent limitations to produce corn silage (Fig. 9).

Fig. 8 Cattle density in natural grasslands and savannas of Argentinean Dry Chaco. Red limits represent the 3-km buffer area from the center of pixels with more 50% of natural grasslands; the gradient between black and yellow inside each buffer is a kernel distance representing density of cattle head ha^{-1} .

In M2 scenario (which incorporate implanted pasture in their fodder resources) average beef production was 10 times higher than in M0; and 3 times higher than M1. The M3 scenario represents the higher productive potential in situations of increasing intensification, obtaining average increases of 3100% in relation to M2 (Fig. 9). In conclusion, sustainable intensification provides many opportunities for increase beef production in the Dry Chaco, across diverse edaphic-climatic conditions. As many of the cattle ranching production in the region occur at small production scales (i.e., 85% of producers and 50% of cattle stock remain in farms with less than 250 heads; INTA, IER, SENASA, 2016) conservation practices which include the exclusion of grazing for prolonged times could impact the subsistence of local farmers. We argue with these results that there exists a broad opportunity to increase beef production through management decision. Governmental initiatives targeting to conserve natural grasslands and savannas or forests in this region, should consider the implementation of processes that improve cattle ranching production, as long as they release pressure on natural environments.

Livestock-Wildlife Interactions

The Chaco hosts an important biological diversity (Bucher and Huszar, 1999; TNC et al., 2005), with around 500 species of birds, 150 species of mammals, 120 species of reptiles and around 100 of amphibians; in addition to 3400 plant species (TNC et al., 2005). It also has a long history of colonization, land-use changes and interactions with wildlife, from subsistence hunting by native people to more intensified practices that expanded in the last decades (Eva et al., 2004; Hoyos et al., 2013). The combination of these practices has resulted in the mentioned replacement of natural grasslands and woodlands with shrubs and eroded areas of bare soil (Baldi and Jobbágy, 2012). Thus, many species occupying the region are in fact mostly associated to open vegetation (Macchi et al., 2013; Marinaro et al., 2015; Torres et al., 2014). However, conservation strategies almost exclusively focus on forests conservation, to the point that protected areas include fire suppression as a management policy, with the consequent woody encroachment (Cardozo et al., 2011; Grau et al., 2014).

Medium-large mammal species of the Argentine Chaco are particularly sensitive to anthropogenic changes, and their sharp decline is mostly attributed to habitat loss and hunting pressure (Periago et al., 2015). Among these species, many seem to prefer

Fig. 9 Beef production ($\text{Kg BW ha}^{-1} \text{ year}^{-1}$) across annual rainfall gradient (gray bars) for different production systems and management scenarios. Base line: Scenario without management practices. Model 1: Scenario including adjusting carrying capacity. Model 2: Scenario including implanted pastures. Model 3: Scenario including corn silage supplementation.

open habitats (e.g., giant anteater, guanaco, manedwolf, large rhea) and their populations may thus be further threatened by forest-centered policies. Medium-large mammals play important, yet understudied functional roles in Chaco ecosystems (Periago et al., 2015). For example, preferential utilization of woody plants by wild browsers (Staver et al., 2009), or seed and seedling predators (Weltzin et al., 1997) may help maintain grassland and savanna communities. The behavior of these herbivores can prevent shrubs and trees from establishing and exerting dominance, and maintain them at a stature vulnerable to fire. On the contrary, woody plants may be in advantage where livestock are effective dispersers of their seeds. In addition, livestock introductions can cause displacement of native browsers and seed predators, releasing woody plants from top-down controls. Preserving populations of native herbivores in systems managed for livestock grazing may help maintain grass-woody populations in desired configurations, while concurrently enhancing biodiversity.

The introduction of cattle early in the 20th century not only affected the balance between woody and herbaceous cover, with several indirect effects on many species, but also gave place to other issues that threaten medium-large mammal communities, such as human-carnivore conflicts due to actual or perceived livestock depredation (Quiroga et al., 2014). The combined effect of traditional hunting and retaliatory/preventive hunting by livestock breeders has already caused the ecological extinction of jaguars in the Argentine Chaco (Quiroga et al., 2014) and is possibly behind the low population densities of the puma, the only other apex predator of the region (Quiroga et al., 2016). Because top-predators have strong top-down effects, the marked decrease in their populations in the Chaco may cause far-reaching changes in the dynamics of its ecosystems.

Conservation and Representation in Protected Areas

Human population is projected to increase from the current ~7 billion people, to ~10 billion people by 2050 (United Nations, 2017). This population growth, translated into an increasing global food demand, strongly threatens natural areas worldwide; particularly in regions such as the Dry Chaco, with strong potential for agriculture expansion (Lambin et al., 2013). However, conservation policies have focused on the threats exerted to forests, at the extreme of neglecting natural grasslands as a specific, and fundamental conservation target (Grau et al., 2014). In addition, these policies may even result in increased pressure over non-forested landscapes, such as natural grasslands (Miles and Kapos, 2008).

The Dry Chaco ecoregion as a whole is rather under-protected. The protected area represents 11.1% of the entire ecoregion, with large differences among the three encompassed countries. Whereas 35.7% of the area is protected in the Bolivian Chaco, the Paraguayan and Argentine Chaco portions barely reach values of 11.8% and 4.8%, respectively. In addition, forests mostly represent these percentages. In the Argentinean portion, only 4.1% of the protected area encompasses natural grasslands, while in Bolivia this value reaches only 0.18%; and in Paraguay, 1.7%. Regarding the relative extension of protected natural grasslands, only 10.1% of Argentine Dry Chaco natural grasslands are protected. In turn, Bolivian native grasslands are protected in a similarly low proportion (9.8%), while in Paraguay this amount increases, with 16.5% of the natural grasslands under protection. We argue that natural grasslands need to be specifically targeted by biodiversity conservation planning, which is not the case in current forest-based initiatives.

Biodiversity in the region is likely very-well adapted to, and even dependent on, natural grasslands and savannas (Grau et al., 2014). Protected areas do not ensure grassland conservation; rather, fire suppression policies that favor woody encroachment are applied, which potentially leads to the disappearance of the grasslands with the highest conservation value (Cardozo et al., 2011). Further, the Native Forest Law of Argentina also ignores the importance of grasslands for many animal species, including species

with high conservation concerns (Grau et al., 2014; Marinaro and Grau, 2015). Identify the “old-growth” natural grassland and savannas (i.e., ancient ecosystems characterized by high herbaceous species richness, high endemism, and unique species compositions) (Veldman et al., 2015) represent an urgent task to identify priority areas of conservation related to natural grasslands and savannas of different typologies.

Future Research and Conclusions

Natural grasslands and savannas are singular components of the Dry Chaco geography spread in different environments and diverse physiognomies, but during the last century they have been seriously reduced and transformed by different human activities that resulted in their replacement by both woody vegetation and agriculture. They have been neglected by the scientific community, in the understanding of their contribution to biodiversity and human livelihoods. Governments, on the other hand, neglected these ecosystems in terms of conservation and management policies. Albeit we elucidate that cattle stocking rates supported by natural grasslands and savannas, particularly in Argentine Chaco, would not represent a major obstacle in terms of production cost at regional scales, the impact of removing the cattle of such areas in terms of livelihoods and rural and indigenous populations' subsistence is not understood and has not been addressed to date. In addition, knowledge of the biological composition, ecological interactions and biogeochemical cycles of natural grassland and savannas transitions (novel ecosystems of implanted pastures, and encroached natural grasslands) should be intensified. The reintroduction of prescript fires not only as a production but also as a conservation tool, the alternatives of restoration practices, and the promotion of ecotourism as sources of income are alternatives whose costs and benefits should also be addressed. We believe that studies in this particular landscape are in initial stages and we encourage continuing understanding these singular ecosystems.

Abstract

Temperate subhumid grasslands extend in the eastern part of South America. This region represents one of the most diverse, largest and less transformed grassland areas in the world. The grasslands occupy the vast and continuous plains of central-eastern Argentina, Uruguay and southern Brazil that surround the Río de la Plata estuary. For this reason, they are referred to as the Río de la Plata grasslands. These grasslands, despite its apparent physiognomic homogeneity, hold high diversity of species, having grasses as the dominant life form except for few scattered shrubs and trees, and show a year-round photosynthetic activity. In this article we describe structural and functional characteristics of the vegetation of the Río de la Plata grasslands. We give an overview on biogeography, ecosystem functioning and services, human appropriation of primary production, disturbances, land use change, biological invasions and conservation status.

Introduction

Temperate subhumid grasslands extend in the eastern part of South America from 28 to 38° Latitude S and from 50 to 66.5° Longitude W. They cover about 760,000 km² and represent one of the most diverse, largest and less transformed grassland areas in the world. They occupy the vast and continuous plains of central-eastern Argentina, Uruguay and southern Brazil that surround the Río de la Plata estuary. For this reason, they are referred to as the Río de la Plata grasslands (Soriano et al., 1992). These grasslands are bordered by deciduous xerophytic forest to the west, and deciduous tropical and subtropical humid forests to the north (Overbeck et al., 2007; Andrade et al., 2018; Oyarzabal et al., 2018). Due to the influence exerted by the Atlantic Ocean, climatic conditions are less extreme than in other regions of the world located at similar latitudes (Paruelo et al., 1995). Average annual temperature varies from 20 °C in the north to 13 °C in the south. The total annual rainfall varies from 1500 mm in the northeast to 400 mm in the southwest, with a lack of seasonal variation and a marked increase tendency in the last decades (Royo Pallarés et al., 2005; Paruelo et al., 2007; Barros et al., 2015).

The grasslands are physiognomically uniform, hold high diversity of species, have grasses as the dominant life form except for few scattered shrubs and trees, and show a year-round photosynthetic activity. Grasslands co-dominated by C₃ and C₄ species are the most abundant physiognomic type, combined with shrublands and forests (Figs. 1 and 2; Boldrini, 1997; Overbeck et al., 2007; Perelman et al., 2001, 2017; Oyarzabal et al., 2018; Lezama et al., 2019a). Steppes occur mainly in the drier western part of the region (Oyarzabal et al., 2018). Prairies and meadows may be locally important under particular topographic and/or edaphic conditions (Burkart et al., 1990; Batista and León, 1992; Perelman et al., 2001; Aragón and Oesterheld, 2008). Savannas become important only in the north ecotones of the regions (Batista et al., 2014). Shrub encroachment may occur, mainly, because of changes in the grazing regime (Altesor et al., 2006; Andrade et al., 2015; Buisson et al., 2019). Forests are mainly restricted to

riparian corridors along the large Paraná and Uruguay rivers and their tributary streams, to rocky hills and ravines, and to azonal soils formed on top of shell debris deposits ([Lewis and Collantes, 1973](#); [Cabrera, 1976](#); [León et al., 1979](#); [Morello et al., 2012](#)).

In this article we describe structural and functional characteristics of the vegetation of the Río de la Plata grasslands. We give an overview on biogeography, ecosystem functioning and services, human appropriation of primary production, disturbances, land use change, biological invasions and conservation status.

Biogeography

Pampa and Campos are the two sub-regions that can be distinguished according to physiognomic, geomorphologic and edaphic features (Soriano et al., 1992). Pampa occurs exclusively in the Argentinean territory, while Campos corresponds to Brazil, Uruguay and a small portion of Eastern Argentina (Fig. 3). From a physiognomic point of view, Pampa has few trees, while Campos includes gallery forests along rivers and woodlands dispersed on hilly areas (Soriano et al., 1992). From a geomorphology standpoint, the Pampa has been formed by thick quaternary loess deposits that have experienced varying degrees of local reworking (Anderson et al., 1999; Ortiz-Jaureguizar and Cladera, 2006). Exceptions to this general pattern are a few isolated uplands in Argentina. In contrast, Campos has been formed of more modern strata on crystalline and basaltic basements, merging or lying near the surface. Here, diverse arrays of older and stable rocks as Precambrian granite, Carboniferous sandstone, and Jurassic basalt have been not fully buried by eolic sediments and exposed to surface and soil-forming processes. In respect to edaphic features, soils in Pampa shift along a west-east gradient, from mollic Entisols with incipient horizon differentiation to well-developed Mollisols with high clay accumulation, high organic matter content and base saturation, very suitable for agriculture (INTA, 1990; Rubio et al., 2019). The lower and flat portions of the landscapes are characterized by the presence of sodic and/or hydromorphic soils, with greater crop restrictions (Lavado and Taboada, 1988; Paruelo et al., 2007). In Campos, the complex array of parent materials and topographic forms has resulted in higher soil heterogeneity than in Pampa (Duran, 1991). This fact probably explains the greater general diversity of plants and number of endemic species in Campos than in Pampa. In Campos, well-developed Mollisols are the predominant soils. Toward the north and east they are associated with Alfisols, Inceptisols, Oxisols, Vertisols and Ultisols, and towards the west with Entisols (Duran, 1991; Paruelo et al., 2007; Streck et al., 2008).

In spite of the apparent uniformity of the vegetation, Pampa and Campos sub-regions can in turn be subdivided in “vegetation units” (Soriano et al., 1992; Oyarzabal et al., 2018; Fig. 3). Vegetation units are areas with relatively homogeneous physiognomy and floristic composition, sharing geomorphic, hydrologic, and edaphic features. Such characterization into vegetation units summarizes and integrates information of the flora at both regional and local scales, generated in the region by more than three generations of botanists and ecologists. We only summarized here the vegetation units based mainly on the seminal description of Rolando León (in Soriano et al., 1992; Oyarzabal et al., 2018). All vegetation units are now partially covered by annual crops, sown pastures or tree plantations (Baldi et al., 2006; Baeza et al., 2014; Baeza and Paruelo, 2018; Andrade et al., 2015; Volante et al., 2015; Modernel et al., 2016). Where land cover has almost completely changed to cultivated cover types, original vegetation can only be inferred from a few isolated remnants of unconverted vegetation and from early, but postcolonial, botanical descriptions. The Pampa sub-region can be subdivided into six vegetation units: Rolling Pampa, Mesopotamic Pampa, Flat Inland Pampa, West Inland Pampa, Flooding Pampa and Austral Pampa (Fig. 3; see more details of each vegetation unit in Soriano et al., 1992 and Oyarzabal et al., 2018). The Campos sub-region has two vegetation units: Northern Campos and Southern Campos (Fig. 3), though this separation is under revision considering the high geomorphological diversity in this region (Hasenack et al., 2010).

(A) Rolling Pampa, (B1) Flat Inland Pampa, (B2) West Inland Pampa, (C) Southern Pampa, (D) Flooding Pampa, (E) Mesopotamic Pampa, (F) Southern Campos, (G) Northern Campos. *Dash lines* are international boundaries (see vector files available in [Appendix 1 of Supplementary material](#)).

Río de la Plata grasslands have high species richness, including many endemic species. The list of all vascular plant species for Río de la Plata grasslands region comprises 4836 species, belonging to 1324 genera and 194 families (Andrade et al., 2018). This total number of species is higher than average per unit area when compared to the entire Southern Cone region (Argentina, Chile, Paraguay, south Brazil and Uruguay), and almost equal to numbers of the savannas in the central region of Brazil, the *Cerrado*. Such high species richness is probably due to its location in a transition zone (Burke et al., 1998). The species richness follows a latitudinal trend. The Brazilian and Uruguayan part hold about twice as many species per unit area as the Argentine part. For every thousand km², there are 20 species in Brazil, 17 species in Uruguay and 9 species in Argentina. About 40% of all species found for the region relies on five families: Asteraceae (659 species; Fig. 4), Poaceae (645; Fig. 5), Fabaceae (399), Cyperaceae (184) and Orchidaceae (149). The endemic species of the Río de la Plata grasslands are 403, corresponding to 159 genera and 49 families (Andrade et al., 2018). Asteraceae and Poaceae are also the two families with the highest number of endemic species, but others much smaller also present a high number of plant endemism: Cactaceae, Iridaceae, Fabaceae, Euphorbiaceae and Amaryllidaceae. Alstroemeriaceae, Bromeliaceae, Erythroxylaceae, Lamiaceae, Passifloraceae have records of endemic species restricted to the Brazilian limits, while Araceae, Caryophyllaceae, Onagraceae and Orobanchaceae were restricted to Uruguay, and just Brassicaceae and Cannaceae presented endemic species only found in Argentina (Andrade et al., 2018).

Vegetation surveys allowed identifying grassland communities within the vegetation units. Starting with the pioneer work of León (1975) and León et al. (1979), different studies characterized floristic heterogeneity of portions of Campos and Pampa sub-regions (Lewis, 1981; Lewis et al., 1985, 1990; Batista et al., 1988; Burkart et al., 1990, 1998, 2011; Fontana, 1996; Lezama et al., 2006, 2011, 2019a). For the Brazilian region of the Campos, three grassland vegetation types and 10 subtypes were classified based on species dominance pattern (Andrade et al., 2019). The classification confirmed the existence of a sharp upper north limit between the Río de la Plata grasslands region and the Highland grasslands, the subtropical grassland ecosystems found in the south and southeast part of Brazil (Andrade et al., 2019). These results give support to an earlier study based on quantitative forest-composition data (Oliveira-Filho et al., 2013). In the Uruguayan portion of the Campos (Fig. 6), the main floristic gradients were associated to edaphic and topographic factors that control water availability. Five communities were identified (Lezama et al., 2019a). Three of the communities correspond to densely-vegetated grasslands associated to medium and deep soils. The remaining two communities were defined as sparsely-vegetated grasslands and were typical of shallow soils (Lezama et al., 2019a,b; Table 1). Such communities presented significant differences in total C gains and in its seasonal dynamics (Baeza et al., 2010; Guido et al., 2014). In the Pampa, 11 communities were identified by Perelman et al. (2001), based on more than 749 relevés. Such communities were in turn classified in five community groups associated to a particular landscape position and soils: mesophytic meadows, humid mesophytic meadows, humid prairies, halophytic steppes and humid halophytic steppes (Table 2; Perelman et al., 2001).

Fossil evidence suggests grazing is not a novel factor in the Río de la Plata Grasslands, considering that grassland ecosystems in South America coevolved with large grazers since ~25 million years (MacFadden, 2006). Further, pollen and charcoal data show that grassland vegetation had dominated during late Quaternary, with forest ecosystems expanding only during the second half of the Holocene. After the large grazer extinctions by the end of the Pleistocene, fire has likely had an important role in maintaining grassland vegetation (Behling et al., 2005; Behling and Pillar, 2007).

Thus, it is expected that, depending on initial conditions and primary productivity, domestic herbivore grazing maintains or changes grassland structure and functioning (Sala et al., 1986; Rodríguez et al., 2003; Altesor et al., 2005, 2006; Semmartin and Oesterheld, 2001; Semmartin et al., 2007; López-Mársico et al., 2015, 2016; Lezama et al., 2014; Fischer et al., 2019). Grazing's effect on vegetation heterogeneity was recognized in the Pampa (Anderson et al., 1970, 1978; León and Marangón, 1980; León and Movia, 1981; León and Anderson, 1983; León and Oesterheld, 1991). As a way to summarize structural and functional changes associated with grazing, several state and transition models were proposed for the region (e.g., Bestelmeyer et al., 2003; Andrade et al., 2015; Buisson et al., 2019). For the humid mesophytic meadows of the Flooding Pampa (Perelman et al., 2001), a model described that changes in plant functional types (prostrated dicots, tall grasses and prostrated grasses) resulted from the combined effects of grazing and floods (Oesterheld and Sala, 1994). For the five communities identified in the Uruguayan Campos (Lezama et al., 2019a), state and transition models were also developed (Altesor et al., 2019). Communities presented an internal heterogeneity associated with changes in total cover, stratification, and proportion of plant functional types. Different states within the same community presented different responses to extreme climatic events. The stocking rate, sheep/cattle ratio, and grazing method are key grazing management strategies that promote the transition among states and phases (Altesor et al., 2019; Fischer et al., 2019).

Table 1 Synoptic table of grassland vegetation in Uruguay at sub-community level.

Community	Sub-community	Physiognomy	Geomorphologic region
I	a. <i>Portulaca papulosa</i> - <i>Selaginella sellowii</i>	One stratum, 2–5 cm tall, dominated by forbs and grasses	Basaltic “Cuesta”
	b. <i>Lippia coarctata</i> - <i>Oenothera parodiana</i>	Two stratus: 5 cm tall, dominated by forbs and grasses; 11–30 cm tall, erect grasses and subshrubs (<i>Baccharis coridifolia</i>)	Basaltic “Cuesta”
II	a. <i>Glechom marifolia</i> - <i>Jarava filifolia</i>	Two stratus: 5 cm tall, forbs and grasses; 30 cm tall, subarbusts and erect grasses (<i>Aristida filifolia</i> and <i>Jarava filifolia</i>)	Eastern Hills
	b. <i>Oxalis conorrhiza</i> - <i>Chascolytrum erectum</i>	Two stratus (typical): 5 cm tall, dominated by forbs and grasses; 30 cm tall, subshrubs (<i>Baccharis</i> sp.)	Eastern Hills
	c. <i>Stenachaenium campestre</i> - <i>Andropogon ternatus</i>	Two stratus (typical): 5 cm tall, dominated by forbs and grasses; 30 cm tall, subshrubs (<i>Baccharis</i> sp.)	South Central region, Eastern Hills, North Eastern Sedimentary Basin
	d. <i>Aira elegantissima</i> - <i>Micropsis spathulata</i>	One stratum, 5 cm tall, dominated by forbs and grasses	Eastern Hills, North Eastern Sedimentary Basin
	e. <i>Paspalum leptoneuron</i> - <i>Hypoxis decumbens</i>	Two stratus (typical): 5 cm tall, dominated by forbs and grasses; 30 cm tall, subshrubs (<i>Baccharis</i> sp.)	North Eastern Sedimentary Basin
III	a. <i>Mecardonia procumbens</i> - <i>Eleocharis dunensis</i>	Two stratus: 5–10 cm tall, grasses; 20–30 cm tall, grasses	Basaltic “Cuesta”
	b. <i>Ruellia morongii</i> - <i>Steinchisma hians</i>	Two stratus: 5–10 cm tall, grasses; 20–30 cm tall, grasses	Basaltic “Cuesta”
IV	a. <i>Eryngium horridum</i> - <i>Danthonia rhizomata</i>	Two-three stratus: 5–10 cm tall, forbs and grasses; 20–30 cm tall, erect grasses and subshrubs. Occasionally, one additional stratum: 100 cm, shrubs.	Eastern Hills (occasionally: South Central region, North Eastern Sedimentary Basin)
	b. <i>Senecio selloi</i> - <i>Nassella pauciciliata</i>	Two-three stratus: 5–10 cm tall, forbs and grasses; 20–30 cm tall, erect grasses and subshrubs. Occasionally, one additional stratum: 100 cm, shrubs.	North Eastern Sedimentary Basin (occasionally: South Central region, Eastern Hills)
	c. <i>Chevreulia sarmentosa</i> - <i>Danthonia montevidensis</i>	One stratum: 5 cm tall, dominated by forbs and grasses. Occasionally, one additional stratum: 30 cm tall, subshrubs.	South Central region, Eastern Hills, North Eastern Sedimentary Basin
	d. <i>Lolium multiflorum</i> - <i>Nassella charruana</i>	Two stratus: 5–10 cm tall, dominated by grasses; 20–30 cm tall, dominated by erect grasses (<i>N. charruana</i>)	(occasionally: Eastern Hills, North Eastern Sedimentary Basin)
V	a. <i>Paspalum pumilum</i> - <i>Chascolytrum poomorphum</i>	Three stratus: 5–10 cm tall, dominated by grasses; 20–30 cm tall, dominated by erect grasses; 50 cm tall, grasses	South Central region, Eastern Hills, North Eastern Sedimentary Basin

Table 2 Landscape and soil characteristics of the main five community groups of the Flooding Pampa, Río de la Plata grasslands.

Community group	Position in the landscape and soil description	Predominant soil types
I: Mesophytic meadows	Positive and convex terrains, highest areas. Deep, well drained soils, acidic, non-saline, poligenic soils	Typic Argiudolls and Poligenetic Thaptoargic Hapludols
II: Humid mesophytic meadows	Flat areas. Intermediate topographic position. Acidic, nonsaline A1 horizon and saline, highly alkaline B2 horizon	Typic Natraquolls with natric B2 horizon Natralbolls
III: Humid prairies	Extended lowlands, with groundwater near the surface, subject to flooding. Soils range from acidic throughout the profile to acidic in the upper and alkaline in the deeper layer Small depressions in flat areas, or rings surrounding humid areas	Argiacuic Argiallbolls Argiacuolls
IV: Halophytic steppes	Very shallow, alkaline soils with very high salt content in the upper layer	Mollic Natraqualls
V: Humid halophytic steppes	Negative positions on fluvial valleys, tidal areas poorly drained. Alluvial, saline sodic soils	Typic Natraqualls

Ecosystem Functioning

Ecosystem functioning varies according to the environmental heterogeneity and gradients in vegetation structure described above. Net primary production and its seasonal dynamics have been identified as key ecosystem attributes able to integrate different aspects of ecosystem functioning, e.g., the exchange of matter and energy between biota and the abiotic environment. Paruelo et al. (2010) summarized different studies on C gains on the Río de la Plata grasslands based on field data, remote sensing techniques and modeling. Aboveground net primary production, as suggested by remote sensing proxies, decreased from NE to SW following the dominant precipitation gradient. Across the precipitation gradient two-fold differences in aboveground net primary production may be expected, from 30 to 750 g DM m⁻² y⁻¹ (Oesterheld et al., 1992). Estimates of belowground net primary production were more variable than aboveground net primary production, and field estimates ranged from 660 to 1420 g DM m⁻² y⁻¹. Total Carbon ranged from 5004 to 15,008 g C m⁻². The largest plant C stock corresponded to belowground biomass. Aboveground green biomass represented less than 7% of the plant C. Soil organic carbon was concentrated in the slow and passive compartments of the organic matter. Active soil pool represented only 6.7% of the soil organic carbon (Fig. 7).

Vegetation units of the Río de la Plata grasslands showed three general patterns of seasonal change of the fraction of the photosynthetic active radiation absorption (fAPAR) as estimated from remotely sensed data (Paruelo et al., 2010). fAPAR is basically determined by the dynamics of leaf area index. The northern most vegetation units (Northern and Southern Campos and Mesopotamic Pampa) showed a relatively low intra-annual variability of fAPAR. A spring peak of fAPAR was evident in these three vegetation units. Inland and Rolling Pampas showed a delayed fAPAR peak and a more marked seasonal variation. The remaining vegetation units (Austral and Flooding Pampas) presented two clear peaks of fAPAR (Paruelo et al., 2010). Photosynthetic active radiation (PAR) presented a well-defined December maximum which determined that the two peaks of some of the vegetation units disappear when absorbed PAR is calculated. Empirical estimates of the radiation use efficiency showed that this coefficient presents minima in summer and maxima in winter (Paruelo et al., 2010, 2019). The seasonal dynamics of radiation use efficiency determined a reduction in the contrast of aboveground net primary production throughout the year. The ratio between maximum and minimum absorbed PAR ranged between 5.45 and 3.12, and between 4.12 and 2.47 for aboveground net primary production (Paruelo et al., 2010).

Regional patterns of primary production are matched by strong patterns of livestock biomass and, consequently, of the proportion of aboveground net primary production consumed by herbivores (Fig. 8). Livestock biomass, a major determinant of

Fig. 7 Carbon balance for the Río de la Plata grasslands. Estimates based on modeling (M), field studies (F), and remote sensing techniques (R) are presented. The values are expressed in g C m⁻² (stocks) and g C m⁻² y⁻¹ (fluxes). Values in parentheses corresponded to the range of observed/simulated values. Abbreviations: ANPP, aboveground net primary production; BNPP, belowground net primary production; POM, particulated organic matter; and MAOM, mineral-associated organic matter. Paruelo, J. M., Piñeiro, G., Baldi, G., Baeza, S., Lezama, F., Altesor, A. and Oesterheld, M. (2010). Carbon stocks and fluxes in rangelands of the Río de la Plata Basin. *Rangeland Ecology & Management* 63(1), 94–108.

net secondary production across the Río de la Plata grasslands, increases more than proportionally as aboveground net primary production increases (Oesterheld et al., 1992). Livestock biomass is six times greater and 0.4 times less variable between years than that observed in natural ecosystems with similar primary production (McNaughton et al., 1989; Irisarri et al., 2014).

Ecosystems Services

Early in the 1990s, the importance of native grasslands on the supply of ecosystem services was highlighted (Sala and Paruelo, 1997). Such ecosystem services include provisioning (e.g., livestock production), regulation (e.g., water, climate and air quality regulation; pollination) and supporting services (e.g., primary production, soil formation). Recently, an integrative index of ecosystem services provision was developed (Paruelo et al., 2016). The index is based on the aboveground net primary production seasonal dynamics assessed through remotely sensed data. The index allows describing the spatial variability of the supply but also temporal trends (Fig. 9). The analysis of the absolute values of the trends over the period 2001–14 showed that almost a third of the

Río de la Plata grasslands presented changes in ecosystem services provision (Fig. 10), most of the trends were negative (Paruelo et al., 2016). Many of those areas corresponded to the agricultural foci identified in both regions (Paruelo et al., 2016). The index of ecosystem services supply presented a negative relationship with a human development index (Paruelo and Dieguez, 2019). It reflects the impact of human activities on ecosystem services.

Human Appropriation of Primary Production

Human impact on the Río de la Plata grasslands is altering ecosystem energy flows, biodiversity, atmospheric composition and the ecosystem capacity to provide services. Human impact on net primary production provides a comprehensive quantification of both aspects of agricultural intensification: increases in cultivated area and crop yield. It quantifies the portion of ecosystems net primary production used directly or indirectly by humans (Vitousek et al., 1986), reflecting changes in available energy for the trophic web (Field, 2001). Forty-two percent of the potential net primary production was appropriated by humans in 2001/2002 in the Río de la Plata grasslands (Baeza and Paruelo, 2018), a value higher than the 15.2% world average estimated by Vitousek et al. (1986). Such percentage in the Río de la Plata grasslands increased 4.5% during the last year due to land use changes.

Disturbances

Four types of disturbances are particularly important in shaping the structure and functioning of Río de la Plata grasslands. First, the type and magnitude of herbivore load determines a pattern of biomass removal, trampling, defecation, and urination with profound consequences for the entire system (Oesterheld et al., 1999). Lezama et al. (2014) analyzed paired grazed and ungrazed plots across a productivity gradient. Compositional dissimilarity between grazed and ungrazed plots, as well as grazing induced differences in plant richness and beta-diversity, all increased across productivity gradient. Plant species richness increased with grazing in high-productive grasslands. Altesor et al. (2006) found that, in contrast with other grasslands worldwide, the absence of grazing promoted shrub encroachment in the Campos subregion. Dominant species were more strongly suppressed by grazing in the most productive grasslands (Lezama et al., 2014).

Continuing with grazing, it may increase or decrease net primary production and soil carbon content in the Río de la Plata grasslands. In the Flooding Pampa, grazed plots presented lower aboveground net primary production than paired ungrazed areas (Rusch and Oesterheld, 1997). In contrast, in the Southern Campos, grazed areas produced more than the ungrazed ones (Altesor et al., 2005). When the initial biomass was the same, ungrazed areas were 29% more productive. Species and plant functional type

composition or biomass vertical distribution promoted by grazing may explain such differences through changes on resource availability, mainly light. Grazed areas showed higher belowground biomass, belowground net primary production and turnover than ungrazed areas (López-Mársico et al., 2015). Studying a network of grazed and ungrazed sites, Altesor et al. (2006) detected a differential effect on the labile and recalcitrant fraction of the soil organic matter due to grazing. Grazing increases superficial soil carbon content, mainly due to the higher belowground biomass in grazed areas. In the deeper soil layer, ungrazed sites showed higher soil C content because of an increase in the more recalcitrant organic matter pool. Piñeiro et al. (2009) hypothesized that changes in soil organic matter content between grazed and ungrazed stands resulted from the balance between root N retention and N loss. Root N retention is due to changes in belowground N allocation patterns. N loss is related to the ability of the soil to retain the extra N available after the exclusion of herbivores and the cessation of volatilization and leaching from urine and dung patches.

Second, the frequency and intensity of fires determines a pattern of biomass removal, nutrient volatilization, and ash deposition which affect the whole ecosystem (Oesterheld et al., 1999; López-Mársico et al., 2019). Spatial distribution of fire events is influenced by the predominant vegetation type and land use in different magnitudes depending on the region. In savannas and prairies, fire density was lowest in areas with a high proportion of agriculture due to the addition of irrigation and fuel reduction practices (Di Bella et al., 2006). Particularly, in the West Inland Pampa, fire as a management practice is excluded by agriculture (Fischer et al., 2012). In the Uruguayan Campos, mainly occupied by grasslands and even when fires are used to improve forage quality, the detected number of fires was insignificant (Di Bella et al., 2006). In contrast, in the Mesopotamic Pampa and in the Argentinean portion of the Campos, fire density was positively associated with the uncultivated land coverage, mainly represented by grasslands (Di Bella et al., 2011).

Third, year-to-year changes, and even larger-scale trends in climate variables, can affect water availability, a major driving force of these systems (Oesterheld et al., 1999). In the Uruguayan Campos, the year-to-year variability in precipitation was higher than the variation in aboveground primary production (Texeira et al., 2019a). The temporal response of carbon gains to precipitation was strong and positive for all land uses (Texeira et al., 2015; Pagnanini et al., 2019). Although there were not clear trends in precipitation, there was a strong negative trend in carbon gains through time, particularly in rangeland of the Northern Campos of Uruguay. These trends represent a decrease of 10–25% of the annual aboveground net primary production (Texeira et al., 2015). Most of these negative trends were associated to seasonality increase and vegetation loss (Texeira et al., 2019b). On the other hand, positive trends in carbon gains through time were associated to grassland afforestation and native forests (Texeira et al., 2015).

Finally, the type and magnitude of nutrient additions generates nutrient concentration, volatilization and lixiviation with effects on the whole system. Nutrient additions are frequent in the Río de la Plata grasslands (García et al., 2002). In the Flooding Pampa, N addition increased the growth of grasses and P addition increased plant P content (Ginzo et al., 1982, 1986; Ginzo, 1983; Collantes et al., 1998; Semmartin et al., 2007). A season $\times$ environment factorial experiment explored the relative importance of mowing, shading and N and P addition as single factors of aboveground net primary production and nutrient dynamics. N addition during spring and summer had the largest and most extended impact on productivity and N and P uptake, whereas P addition, mowing and shading had a lower effect. Three species groups differentially accounted for these responses (Semmartin et al., 2007).

Land Use Change

The Río de la Plata grasslands experienced a profound transformation through the last four centuries. Starting with European colonization, agriculture expanded, mainly since the early years of the 20th century due to European immigration. The main land-use changes that took place in the region include the replacement of grasslands by annual and forage crops, the replacement of grasslands by tree-plantations, and grazing intensification in native grasslands (Paruelo et al., 2007). Though summer drought restricted in the past annual crops expansion in the western edge of the area, nowadays the spatial variability in cropped area is associated with soil restrictions, particularly salinity and soil drainage in the Flooding Pampa and soil depth in the Campos. Grassland cover was reduced from 67.4 to 61.4% between 1985 and 2004 (Baldi and Paruelo, 2008). During the first decades of the 21st century this trend accelerated (Baeza and Paruelo, 2018; Fig. 11). The increase observed was associated, mainly, to the expansion of double-crops systems (Volante et al., 2015). Afforested area with exotic species, mainly of *Eucalyptus* and *Pinus* genera, also expanded in the Río de la Plata grasslands, mainly in the Northern and Southern Campos and the Mesopotamic Pampa (Baldi and Paruelo, 2008). From 1984 to 2004 tree plantations increased the area occupied from 6.7% to 8.6%. With climatic change, even more critical scenarios are expected for the next decades, due to the growing pressure for food production, particularly soybean (Caetano et al., 2018).

Floods can be one of the consequences of replacing perennial vegetation by annual crops. The replacement of perennial alfalfa pastures by annual crops in the Inland Pampa changes the hydrology functioning. Perennial pastures had higher annual transpiration rates (1075 mm y^{-1}) than double winter/summer crops (778 mm y^{-1}) and single summer crop (679 mm y^{-1}). Significantly deeper water-table levels in pastures compared to single and double cropping (4, 1.5 and 2.1 m, respectively) were suggested by hydrological modeling and confirmed by field observations (Noseto et al., 2015). Field studies suggested enhanced groundwater recharge in croplands and direct groundwater discharge by pastures. Soil profiles, being notably drier under pastures (316 vs. 552 mm stored at 0–3 m depth), prevented the recharge episodes experienced by agricultural plots after an extraordinary rainy

Fig. 11 Land use/land cover maps for Río de la Plata grasslands in two periods. Letters denotes vegetation units as subdivisions of subregions Pampas (A, B1, B2, C, D and E) and Campos (G and F). Forage resources are perennial and Forests include afforested areas and native forests. *Dash lines* are international boundaries. Modified from Modified from Baeza, et al. (2018). Spatial and temporal variation of human appropriation of net primary production in the Río de la Plata grasslands. *ISPRS Journal of Photogrammetry and Remote Sensing* **145**, 238–249.

period. The studies from [Noseto et al. \(2015\)](#) indicated that land-use has a direct impact on the hydrology of the subhumid hyperplains of the Pampa, supporting the linkage of groundwater level raises and flood frequency and severity increases with the expansion of grain production systems in the region ([Fig. 12](#)). Floods reduced thermal range and longer frost-free periods ([Houspanossian et al., 2016](#)).

Compared to grasslands, tree plantations had higher primary production ([Vassallo et al., 2013](#)). This production increase was accompanied by higher evapotranspiration rates ([Nosetto et al., 2005](#)) and a lower water yield, responsible of halving stream flow in afforested watersheds ([Jobbágy et al., 2006](#)). In some areas of the Pampa, trees used groundwater increasing the salinity of deep soil and the water table ([Jobbágy and Jackson, 2004](#)).

Fig. 12 Relationship between water-table depth and flooded area (top), and Landsat images showing the flooded area in two contrasting dates (bottom), in the core of the Flat Inland Pampa, Río de la Plata grasslands. Modified from Noseto, M. D., Paez, R. A., Ballesteros, S. I. and Jobbágy, E. G. (2015). Higher water-table levels and flooding risk under grain vs. livestock production systems in the subhumid plains of the pampas. *Agriculture, Ecosystems and Environment* 206, 60–70.

Biological Invasions

Of the entire 4864 species of the Río de la Plata grasslands flora, 496 species are exotic (10%) (Andrade et al., 2018). Poaceae, Asteraceae and Fabaceae were the families with the highest number of invasive species, and herbs were the most common life form (Fonseca et al., 2013). Most invasive plants originated from Europe, Asia and Africa, and almost one-quarter of the species are associated with some human use, especially gardening (Fonseca et al., 2013; Poggio et al., 2015). Some invasive species have a very wide distribution, such as *Eragrostis plana* Nees. (capimannoni 2) in the Campos (Medeiros and Focht, 2007; Barbosa et al., 2013; Guido et al., 2016; Caetano et al., 2018) and *Festuca arundinacea* Schreb. (tall fescue) in the Pampa (Scheneiter et al., 2015). In the Pampa, 18–32% of the species are exotic (Fig. 13), while only 4–7% are in the Northern Campos (Chaneton et al., 2002; Lezama et al., 2006; Perelman et al., 2001, 2007, 2017; Bresciano et al., 2014).

Different communities could present a different degree of vulnerability to invasion. In the Northern Campos, the level of grassland conversion into agriculture at the surrounding landscape is one of the main factors driving invasion in grassland remnants (Guido et al., 2016). In the hydromorphic prairies and halomorphic steppes of the Flooding Pampa, the invasion resistance of these communities may be related to flooding events, since there are few exotic species that arrived to the region adapted to conditions so extreme. Consequently, it is observed that the richness of exotic species decreases with the stress level of the soil environment: higher electrical conductivity or lower depth of the surface horizon (Perelman et al., 2007; Fig. 14). In contrast, in the humid mesophyte meadows, where the abiotic conditions are more benign, the resistance to the invasion is generated by a group of native species, the summer perennial grasses (Perelman et al., 2007; see also Bresciano et al., 2014). Most exotic species that invade these grasslands correspond to annual cool-season species, for which it is not expected that their adult individuals will be displaced by the competition of summer perennial grasses. However, towards the end of summer, the large biomass produced by summer grasses interferes with germination and installation of exotic annual cool-season species (Perelman et al., 2007).

Fig. 13 Mean percentage number of exotic species for five latitudinal grassland areas belonging three vegetation units of the Río de la Plata grasslands. Bars are SE. Means labeled with different letters differ at $P < .05$ (Tukey test after ANOVA). Perelman, S., Burkart, S., Oyarzabal, M., Bagnato, C. and Batista, W. (2017). Climatic and land use drivers along a latitudinal gradient: Species diversity in temperate grasslands on agricultural soils. *Journal of Vegetation Science* **28**(6), 1097–1269.

Fig. 14 Relationship of native and exotic species richness with (A) topsoil electrical conductivity (ln-transformed), and (B) depth of soil upper layer. All regressions are significant at $P < .001$. Perelman, S. B., Chaneton, E. J., Batista, W. B., Burkart, S. E. and León, R. J. C. (2007). Habitat stress, species pool size, and biotic resistance influence exotic plant richness in the flooding Pampa grasslands. *Journal of Ecology* **95**, 662–673.

Conservation Status

Four aspects evidence that conservation initiatives in the Río de la Plata grasslands are insufficient. First, most of grassland remnants are located in private properties and under immediate threat of conversion to other land use (Pillar and Vélez, 2010; Bilenca and Miñarro, 2014). Second, despite the vast tradition in botanic and floristic studies (Cabrera, 1976; Perelman et al., 2001, 2017, 2018; Lezama et al., 2006, 2019a, 2010), a red list of grassland species and communities is lacking in Uruguay and Argentina (Berg et al., 2014). Third, the number of protected areas is low, 38 in the Pampa and 61 in the Campos. Such areas covered 3.7% and 6.8% of each subregion area (UNEP-WCMC, 2019), figures below the proportion recommended (10–15%). The selection of these protected areas has been fundamentally opportunistic, based on preexisting and low cost public areas (Overbeck et al., 2007; Baldi et al., 2017, 2019). Finally, grazing and fire disturbances are essential part of the dynamics of grassland ecosystems as described above (Fig. 15). These disturbances contribute to the maintenance of its high biological diversity (Pillar and Vélez, 2010). However, this subject is yet a taboo in conservation of grassland ecosystems (Overbeck et al., 2015), and consequently conservation practices could be ineffective.

Abstract

The matorral or Mediterranean scrub biome occurs within a narrow band of central Chile between approximately 30 and 38°S latitude. Bounded on the east by the Andean Cordillera and on the west by the Pacific Ocean, the area is characterized by a winter-wet, summer-dry climate, generally frost-free winters, and prolonged summer drought. A diverse flora includes many sclerophyllous shrubs, some drought-deciduous ones, and an herbaceous understory during winter and spring months. However, within the latter, exotic species which have become naturalized now make up a substantial proportion of the ephemeral flora. Matorral perennial shrub vegetation displays considerable endemism, and is structurally convergent with Mediterranean scrub in California, Spain, and the Mediterranean Basin. Among higher vertebrates, herptiles, birds and small mammals exhibit broad geographic ranges in the matorral and lower species turnover between habitats (β -diversity) than in other Mediterranean scrub areas. Despite low taxonomic affinity, similar to perennial shrubs, there is convergence in major body types, feeding guilds and foraging techniques. Due to anthropogenic disturbance including clearing, fire, and extensive overgrazing/browsing, there are relatively few intact examples of undisturbed matorral left, and greater effort needs to be expended to preserve this highly unique biome. Long-term studies at a thorn scrub site on the northern edge of the matorral suggests that altered rainfall patterns have led to changes in the small mammal assemblage composition. Over time, such effects may also become manifest in the central Chilean matorral.

Introduction

The Chilean Mediterranean shrubland or matorral occurs in a narrow band of the central part of the country between approximately 30° and 38°S latitude from sea level to ca. 1500 m (Rundel, 1981; Armesto et al., 2007). The term “matorral” is used in a broad sense, as it encompasses a wide variety of vegetation assemblages resulting from plant responses to the great diversity of environmental gradients that can be found along the Mediterranean region of Chile (central Chile). This environmental diversity is determined by the combination of high topographic heterogeneity (with the Andean Cordillera to the east, the western Pacific shore, and the intervening Central Valley), a latitudinal aridity gradient (with the Atacama desert at the northern limit and temperate forest at the southern limit), and the presence of the cold Humboldt Current (Rundel, 1981; Luebert and Plissock, 2006; Armesto et al., 2007).

The climate here is characterized as Mediterranean-type with winter-rain summer-drought seasons and generally frost-free conditions (Mooney et al., 1977). The Humboldt Current results in typically dry conditions except in winter; the lack of convective thunderstorms in summer as well as the presence of the high Andes as a rain-shadow is a further hindrance to moisture, especially in summer months. Similar to the structurally convergent chaparral of California and Baja California, the Chilean matorral is strongly influenced by aperiodic episodes of high rainfall as a consequence of the El Niño Southern Oscillation (ENSO) (Armesto et al., 2007). In Chile during such periods, the cold Humboldt Current is displaced vertically resulting in warmer onshore winds and more rainfall during the winter.

The matorral is characterized by a mixture of drought-deciduous and evergreen sclerophyllous shrubs and trees, and a diverse herbaceous plant assemblage (Fig. 1; Armesto et al., 2007). Much of the original biome has been extirpated, and degraded matorral or *espinal* characterizes much of the Central Valley where the terrain now is dominated by thorn acacia (*Vachellia caven*) forming extensive savannas (Rundel, 1981). Many exotic weeds have been introduced due to human activities (Arroyo et al., 2000). In central Chile, 18% of the flora is composed by naturalized species and in some matorral communities alien plants can reach 80% of the total herb abundance (Arroyo et al., 2000; Gómez-González et al., 2011).

As a consequence of a long history of land use change, frequent wildfires and plant invasions, today the matorral has serious conservation problems; less than 30% remains intact, and only 10% is protected (Myers et al., 2000). Well-preserved examples

Fig. 1 Typical matorral with xerophytic species on north-facing slopes and sclerophyllous woodlands on south-facing ones. Photo: F. Ojeda.

of matorral occur in isolated areas (e.g., Parque Nacional Las Palmas de Cocalán near Valparaíso, Parque Nacional La Campana, Reserva Puquén in Los Molles); on the northern edge of the matorral, a notable intact thorn scrub community occurs in Parque Nacional Bosque Fray Jorge (henceforth Fray Jorge). Although not strictly matorral, it may provide insight into the ongoing processes there.

Herein, we review the history, biogeography, and composition of Chilean matorral, the role of anthropogenic disturbance, and conservation status with particular emphasis on its flora and vertebrate fauna. Finally, we discuss salient patterns that have emerged at a well-studied site in Fray Jorge.

History and Geography

The location of the matorral in central Chile is a product of two important geographical features which affect all communities on the west coast of South America: proximity to the Pacific Ocean, and the Andean cordillera. Running N to S in a narrow strip no more than 120 km wide, the biome occupies a region whose climate is strongly influenced by the offshore flow of the Humboldt Current bringing extremely cold Antarctic water northward. This has the effect of cooling eastward-flowing air (which is accentuated by strong seasonal upwellings; [Escribano et al., 2003](#)), thus reducing its moisture capacity—particularly in warm summer seasons—and leading to a single rainy season in winter ([Armesto et al., 2007](#)). The orogeny of the Andes was initiated in the late Mesozoic, but the greatest uplift has been in the past 30 Mya ([Orme, 2007](#)). Beginning about 14 Mya, the Andes isolated present-day Chile from the rest of South America and created the Arid Diagonal (sensu [Abraham et al., 2000](#)). This determined the appearance of the Atacama Desert on the west side of the Andes in northern Chile (one of the driest and oldest deserts in the world; [Rundel et al., 2007](#)) and of the Mediterranean region further south with the development of the sclerophyllous vegetation ([Hinojosa and Villagrán, 1997](#)). It has been proposed that many plant species of the matorral have their origins in drought-adapted vegetation similar to that in the Chaco, the Monte and the Andean PrePuna ([Hinojosa and Villagrán, 1997](#); [Armesto et al., 2007](#)). Some genera were already present during the Tertiary, under a tropical climate (e.g., *Peumus*, *Lomatia*), while others resulted from evolutionary processes that occurred after the Andes uplifted (e.g., *Schinus* and *Puya*) ([Hinojosa and Villagrán, 1997](#); [Rundel et al., 2016](#)). For some faunal elements such as terrestrial mammals, the Andes have been at once a barrier, a center of diversification, and a dispersal corridor ([Raven, 1973](#); [Meserve and Glanz, 1978](#); [Meserve, 2007](#)).

Flora

The Chilean matorral has high floristic richness and a diversity of plant communities due to its environmental heterogeneity ([Arroyo et al., 1999](#)). This heterogeneity is a result not only of the presence of two mountain ranges running N-S (i.e., the coastal range and the Andes), but also the relatively broad latitudinal range of the biome. There is a high degree of endemism, especially at the generic level, as a consequence of the age and geographic isolation of this biome ([Fuentes et al., 1995](#)).

Fig. 2 Arid matorral at Reserva Puquén de Los Molles, Punta Los Molles, Chile. The community here includes many succulents as well as sclerophyllous shrubs and cacti in protected areas. Photo: P. L. Meserve.

According to [Luebert and Plissock \(2006\)](#), the Mediterranean zone of Chile includes six different ecosystem types from north to south (with many subtypes depending on the distance to the shore and altitude), but we can summarize them in three main types: (1) the arid matorral ([Fig. 2](#)), located in the Coastal Range from the south of Coquimbo to Valparaíso, dominated by endemic xerophytic shrubs such as *Flourensia thurifera*, *Bahia ambrosioides*, *Heliotropium pycnophyllum*, and *Colliguaja odorifera*, cacti (e.g., *Copiapoa* and *Eulychnia* spp.) and bromeliads (e.g., *Puya chilensis*); (2) the thorny matorral ([Fig. 3](#)), composed of spiny trees like *Vachellia caven*, and *Prosopis* spp., and xerophytic shrubs (e.g., *Trevoa* and *Baccharis* spp.); and: (3) the sclerophyllous matorral ([Fig. 1](#)), which contains the most typical matorral shrubs and trees, such as *Cryptocarya alba*, *Lithraea caustica*, *Peumus boldus*, *Schinus latifolius*, *Quilaja saponaria*, *Maytenus boaria*, *Kageneckia angustifolia*, and *Azara integrifolia*, among others ([Luebert and Plissock, 2006](#)). In the northern part of the Mediterranean region (31–35°S), thorny scrublands alternate with sclerophyllous woodlands (and relict populations of the Chilean palm, *Jubaea chilensis*, in the Valparaíso region; [Figs. 1 and 3](#)), while in the southernmost zone (36–38°S), sclerophyllous forests mixed with broadleaf evergreen and deciduous forests can be found forming a highly diverse ecotone in the Mediterranean-temperate climatic transition ([Luebert and Plissock, 2006](#)).

Fig. 3 Thorny matorral dominated by *Vachellia caven* and a relict population of the Chilean palm (*Jubaea chilensis*), in Parque Nacional La Campana. Photo: J. Pausas.

There are strong physiognomic similarities among sclerophyllous shrubs in Chile and California, as well as in southwest Africa, Australia, and the Mediterranean Basin (Mooney et al., 1977; Young et al., 2007), but these are due to convergent evolution in similar climates rather than taxonomic affinity (Arroyo et al., 1995). However, the geographic isolation and the virtual absence of fires in Chile has resulted in a relatively less species richness (~3000) in the matorral compared to other Mediterranean-type ecosystems (Rundel et al., 2016). This isolation has generated a high degree of endemism at the generic level (Fuentes et al., 1995).

Floristically, the perennial shrubs and native ephemerals in the Chilean matorral are among the most distinctive in South America, with almost 60% endemism (Young et al., 2007). Although some notable congeners appear in both North and South America (e.g., *Larrea* spp., *Prosopis* spp., *Vachellia* spp.) none are dominant elements in the matorral except for *Vachellia* in the *espinal*. The evergreen shrub *Porlieria chilensis* (guyacán), which dominates the thorn scrub community in Fray Jorge at the northern end of the Chilean matorral, is believed to be of Andean origin (Solbrig et al., 1977) and is in the same family (Zygophyllaceae) as the widespread *Larrea* spp. of northwestern Argentina and southwestern United States.

Fauna

Three faunal groups—reptiles, birds, and small mammals—are particularly useful for illustrating the effects of isolation and spatial heterogeneity on their distributions and local (α or alpha) diversity in the Chilean matorral. While all three groups received a pulse of research activity in the 1970s, subsequent work on reptiles and birds has been surprisingly limited.

Continental Chile hosts five species of snakes and about 120 species of lizards (Ruiz de Gamboa, 2016), the vast majority of which (about 96) are in the extremely diverse genus *Liolaemus* (Liolaemidae). Of these, two snake and about 23 lizard species occur in Mediterranean Chile (Cody et al., 1977; Fuentes et al., 1995; Ruiz de Gamboa, 2016; Uetz, 2019). Fuentes (1976) showed that lizards occurring in the Mediterranean scrub of Chile and California exhibit strong convergence in habitat use, diet, and species turnover between habitats (β -diversity). In particular, he described strong one-to-one matches in the niches of taxonomically-unrelated lizards across these regions. In Fray Jorge, up to 6–8 lizard species occur sympatrically, occupying both the thorn scrub and higher elevational shrub communities in the park (Minn, 2000; Albiñana, 2005). These species range in diet from carnivory (*Callopistes maculatus* [Chilean iguana or tegú]) to insectivory and herbivory (*Liolaemus* spp.). Remarkably, *Callopistes* were more numerous in experimental plots from which avian and mammalian predators were excluded, and they appear to depress numbers of smaller (prey) lizards (Minn, 2000). These observations were not repeated in a second field season, but they comprise a compelling call for further research.

Of about 315 terrestrial bird species known from Chile (Vilina and Cofré, 2006; Jaramillo and Barros, 2013; Couve et al., 2016; Remsen et al., 2019), 108 to 127 (Jaramillo, 2003; Couve et al., 2016) occur in the Mediterranean region. The Chilean matorral has fewer birds than Mediterranean scrub in California (Cody et al., 1977), although α -diversity is similar, indicating that Chilean birds occur in a broader range of habitats, such that species turnover (β -diversity) among habitats is distinctly lower (Cody et al., 1977). Longer-term studies in Fray Jorge (Kelt et al., 2012, 2016) reported 63 species from triennial surveys, suggesting that earlier estimates for the matorral were a significant underestimate due to failure to incorporate periods when birds migrate in from Andean foothills, and during periods of high rainfall associated with ENSO events, and on-going climatic change. In spite of intriguing ecological comparisons between birds of Chile and rather distantly related passerine species in the Northern Hemisphere (e.g., tit-spinetails (Furnariidae, *Leptasthenura*) and tit-tyrants (Tyrannidae, *Anairetes*) versus holarctic parids (Paridae, e.g., tits, *Parus*, or chickadees, *Poecile*) or regulids (Regulidae, *Regulus*); (Ridgely and Tudor, 1994; Jaramillo, 2003), very little comparative behavioral work has been pursued (but see Engilis and Kelt, 2009, 2011). Another intriguing parallel with other arid/semiarid regions is the mutualism between the endoparasitic mistletoe *Tristerix aphyllus*, two species of columnar cacti (*Echinopsis chilensis* and *Eulychnia acida*), and the Chilean mockingbird (*Mimus thenca*; see Kelt et al., 2016). Unlike many other bird-mistletoe associations, however, the *Tristerix-Mimus* relationship is highly asymmetric as the Chilean mockingbird retains a relatively diverse diet and is not tightly bound to the mistletoe for food (cf. Watson and Rawsthorne, 2013).

Cody et al. (1977) and Fuentes et al. (1995) reported on small mammal trends in Chilean matorral; 5–10 species may occur in different matorral habitats resulting in similar α -diversity as in California. However, as is the case for birds, small mammal species in Chile occur in a wider variety of habitats, resulting in lower β -diversity. Also, small mammals show dispersion of feeding specializations (granivory, herbivory, insectivory, omnivory; Glanz, 1976; Meserve, 1981), and in most instances where multiple species share similar diets, one is much more common than the other (Meserve and Le Boulengé, 1987).

The ecological equivalent of fossorial gophers (*Thomomys*, Geomyidae) in California Mediterranean scrub is the endemic cururo (*Spalacopus cyanus*, Octodontidae) in coastal range matorral and Fray Jorge. This rodent specializes on geophytic bulbs, and its colonial activities can alter significantly the composition of the herbaceous community by generating important soil disturbances at the landscape scale (Contreras and Gutiérrez, 1991; Torres-Díaz et al., 2012).

Disturbance

The current physiognomy and composition of the Chilean matorral cannot be understood without considering the role of human disturbance. The landscape of central Chile has been dramatically transformed since Spanish colonization, particularly from the 19th century to the present. After many years of intensive grazing, vegetation removal, and burning, vast areas of matorral have

Fig. 4 Invasion of *Eschscholzia californica* in a disturbed matorral in the Central Valley near Til-Til. Photo: P. L. Meserve.

been converted to degraded habitats, highly susceptible to alien plant invasion and erosion (Arroyo et al., 2000; Fig. 4). Land use change has significantly reduced the distribution of native sclerophyllous shrublands in central Chile since it is a key region for agriculture, livestock, and forestry, and supports ca. 80% of the total population (Heilmayr et al., 2016; Miranda et al., 2017). A consequence of this elevated human pressure and the Mediterranean-type climate is the occurrence of wildfires, which are increasing in frequency and magnitude with climate change (González et al., 2018). Unlike the other Mediterranean-type biomes of the world, natural fires are rare in Chilean matorral, and fire adaptations are less frequent in the flora (Montenegro et al., 2004; Gómez-González et al., 2017). Although the most common woody species are able to resprout after fire (e.g., *Lithraea caustica*, *Quilaja saponaria*, and *Peumus boldus*), post-fire germination and seedling recruitment is scarce (Muñoz and Fuentes, 1989; Segura et al., 1998). Many fire-intolerant species are endemic and therefore carry important conservation value (e.g., *Azara petiolaris*, *Cryptocarya alba*, *Kageneckia angustifolia*, and *Podanthus mitiqui*; Gómez-González et al., 2017). Therefore, fire reduces woody plant diversity (Armesto and Gutiérrez, 1978) and favors the development of annual grasslands dominated by alien species (Gómez-González et al., 2011).

Besides wildfires, the matorral is subjected to high pressure from exotic herbivores (livestock and naturalized European rabbits [*Oryctolagus cuniculus*] and hares [*Lepus europaeus*] Holmgren, 2002). These herbivores can also favor alien plant invasion and limit the establishment of the seedlings of native woody species in open microhabitats (Fuentes et al., 1984; Holmgren, 2002). Therefore, active restoration has been recommended to overcome the recruitment limitations of native species in the matorral (Armesto et al., 2009). Currently, a national restoration program is needed to recover the biodiversity and generate more sustainable landscapes that improve social adaptation to frequent wildfires and climate change.

Conservation

As noted previously, the Chilean matorral is considerably reduced in area due to its location near the most populated and accessible parts of central Chile. Historically, with relatively little montane vegetation there, much of the sclerophyllous woodlands were rapidly cleared for construction material, and matorral was burned for charcoal production in colonial times (Rundel, 1998). Further, many remaining areas were greatly altered by goat overgrazing resulting in extensive *espinal* savannas today in the Central Valley. On the north end of the region known as the “Norte Chico,” extensive areas of denuded shrublands now exist with little prospect of recovery (Bahre, 1979). A concerted effort for “reforestation” of such areas by the Chilean government and conservation/park agencies (e.g., CONAF) has resulted in a monotonous landscape dominated by exotic saltbush (mostly *Atriplex nummularia*) which supports few birds or mammals (Kelt and Meserve, 2016). On the other hand, extensive forest plantations of *Eucalyptus* spp. and *Pinus* spp. have contributed significantly to the loss of native vegetation in the Mediterranean zone of Chile, particularly in the Coastal Range of the Maule Region, where the matorral and the temperate rain forest meet to form a highly diverse ecotone (Heilmayr et al., 2016; Miranda et al., 2017). In the current scenario of warming and drought, the transformation of native forests into plantations and agricultural areas is increasing fire risk and damage at landscape scale (González et al., 2018; McWethy et al., 2018; Gómez-González et al., 2019), contributing to the degradation of contiguous natural areas of elevated conservation value.

Without a concerted effort to set aside significant new areas for preservation, the prospects for conservation of the matorral's biota are dim, especially given the high degree of endemism and increasingly endangered plants and animals there (e.g., [Squeo et al., 2001](#)). Further, with increasing evidence of the impact of climate change on Mediterranean-type ecosystems (e.g., [Oechel et al., 1995](#); [Hilbert and Canadell, 1995](#)), there is great urgency for such efforts.

Fray Jorge, a Sentinel Site

Since 1989, a long-term field manipulation has been in progress at a thorn scrub site on the northern edge of the Chilean matorral ([Fig. 5](#)). This experiment has focused on identifying and quantifying factors influencing community dynamics including biotic interactions (i.e., vertebrate predation, herbivory, interspecific competition) and abiotic factors (i.e., rainfall, climate change). Results from this multifaceted project have been reported elsewhere (e.g., [Kelt et al., 2016](#); [Meserve et al., 2016a,b](#)), and are only briefly summarized here. They highlight the importance of long-term studies in this region, and the increasing evidence for, and impact of, ongoing climate change.

The initial focus of this research was on the role of biotic interactions in small mammal populations, and indeed, evidence for strong predator effects on elements of the small mammal assemblage have been demonstrated, but these effects were transitory in nature and predation neither prevented small mammal increases nor accelerated their decline. At the same time, important effects of a small mammal herbivore (the degu, *Octodon degus*) on Mediterranean scrub vegetation have been documented (e.g., [Gutiérrez et al., 1997](#); [Gutiérrez and Meserve, 2000](#)) and we tested the effects of food addition on this and other small mammal species ([Meserve et al., 2001](#)). In the latter study, food addition did not elicit responses by *O. degus* and another herbivore, Darwin's pericote (*Phyllotis darwini*), during a high rainfall year, but did induce increases in a drought year. Overriding these results, however, is the importance of background climatic events such as ENSOs on the majority of small mammals of this community. In 2000–02, a prolonged high rainfall event led to record increases in degu populations, and degu numbers and biomass have remained high in ensuing years instead of returning to previously lower numbers ([Meserve et al., 2016a](#)). This suggests that a fundamental shift may have occurred in the small mammal assemblage, leading to a new stable point; [Scheffer \(2009\)](#) has termed this a "critical transition." We suggest that the pattern of somewhat lower average annual rainfall with markedly reduced interannual variation may be responsible for this shift. Long-lived small mammal species such as *O. degus*, formerly unable to increase cumulatively because of long intervals between high rainfall events and periodic drought periods, were able to maintain high populations because of more predictable (albeit lower) annual rainfall. On the other hand, recent accentuation of differences in mean annual rainfall may indicate a return to previously existing conditions.

Whether other community elements will experience such a transition in the near future remains to be seen, but we have seen evidence for increased interactions between native and exotic ephemerals as well as between native small mammals and exotic lagomorphs (*Lepus europaeus* and *Oryctolagus cuniculus*) at this site. These novel interactions are playing out a period of dramatic climate change in the region, and it remains uncertain how these will play out in the coming decades. Ongoing work at Fray Jorge, now in its 32nd year, continues to provide surprises and insight as we monitor this system.

Abstract

One of the richest hotspots of the world is the Mediterranean floristic region with over 24,000 species distributed in the large territory (2,300,000 km²) of the Mediterranean Basin. High numbers of genera (around 2000) and families (around 200) have been recorded, which gives this region the richest figures of the five mediterranean floristic regions of the world. All these taxa group together into numerous habitats (c. 150) and vegetation types brought about by main abiotic (climate, soil types and altitudinal gradients) and biotic (autoecology and ecological interactions) characteristics. This chapter summarizes floristic and vegetation richness over the last geological epochs, considering historical biogeography and past climatic events, which have shaped the distribution of plants in southern Europe and northern Africa. Time-calibrated phylogenies and the fossil record help interpret a long period of extinctions of Tertiary lineages in the Neogene giving the opportunity of speciation to other plant groups. Vegetation arranged into five vegetation belts (thermo-Mediterranean, meso-Mediterranean, supra-Mediterranean, oro-Mediterranean, cryoro-Mediterranean) is understood as a dynamic ecological succession in which vegetation transition occurs in a predictable series of grasslands, shrublands and woodlands.

Predictable Climate

There exist some seasonal characteristics that make any mediterranean climate predictable. Since the establishment of the mediterranean climate in the Old World about 2.8 millions of years ago, a long hot summer is expected every year. Any mediterranean-type biome of the world is located in southwest territories of most continents (California, Chile, South Africa, Australia and the Mediterranean Basin) and characterized by a long drought when temperatures are the highest (summer) (Fig. 1A). This is why fire is particularly lethal during summer months. Strategies of fire persistence in woody shrubs, annuals and geophytes are common, albeit less remarkable than those of other Mediterranean floristic regions such as South Africa (Rundel et al., 2018). Main rainfall occurs in autumn, winter or spring depending on country location. Indeed, rainfall and temperature regimes are not homogeneous across a large territory such as the Mediterranean Basin (Fig. 2). On the one hand, temperatures significantly vary depending on proximity of the areas to the Mediterranean Sea that always buffers low temperatures in winter, while inland areas suffer from more extreme day/night and winter/summer changes in temperatures. On the other hand, rainfall is also related to sea and ocean proximity where precipitation is generated by favorable atmospheric currents. Western areas have a strong oceanic (Atlantic) influence that diminishes eastwards. Eastern areas are influenced by precipitation primarily generated from the Mediterranean Sea and occasionally after the monsoon season (Giannakopoulos et al., 2011; Lionello and Sanna, 2005).

The elevational gradient in mountains consists of a decrease in temperature at increasing elevation (about 0.8°C mean average every 100 m.a.s.l.). Mountains provide not only lower temperatures but also higher rainfall, which give high altitude areas more similar conditions to those of the Eurosiberian floristic region (Fig. 1). In contrast, numerous mountains bring about rain shadows producing drylands on southern slopes (e.g. the Spanish Almería desert and the Moroccan Anti-Atlas) and extreme deserts out of the Mediterranean floristic region (e.g. south of the Mediterranean Basin). Lack of sufficient rainfall because of the influence of the largest desert of the world (Saharan dessert) also makes extreme deserts in some African areas nearby the Mediterranean coast (Fig. 2). Capes and islands buffer temperatures because they are embedded in the influence of the Mediterranean Sea.

All these characteristics make significant differences in a large territory such as the Mediterranean Basin, even though a summer drought takes place every year in every country. Indeed, climate is highly predictable in terms of both temperature and rainfall at a local scale. However, the effects of climate change on plants have been already detected (Aguilera et al., 2015). Flowering phenology is one of the variables most used to assess quick plant response to climate change. Although precipitation is involved in flowering variation, temperature affects the most plant species in flowering phenology across the Mediterranean Basin (Petanidou et al., 1995; Gordo and Sanz, 2010).
